"The sounds given out by orchestral instruments have been investigated by recording the air pressure fluctuations in each wave. These waves are then analysed by Fourier analysis, either mathematically or experimentally, and the harmonics present are found and their relative intensities. (The problem is identical with that of tidal analysis.)

"The Hammond organ can undoubtedly produce a wealth of tone shades different from those of any known instruments. I found it most interesting when experimenting with it to alter a tone in a series of steps (each of which was in itself practically imperceptible) from that of a clarinet to that of the flute or oboe."

Industrial Use of Electric Batteries

ELECTRICAL engineers have recently been considering the relative merits of vehicles driven by electric batteries and of those driven by petrol. Considerable difference of opinion exists on this point, and so the paper by Dr. Strohe, of Cologne, a translation of which appears in *World Power* of June, is of value as he gives the results of practical tests on the two classes of vehicle.

Dr. Strohe summarizes the relative performances of an electric and a petrol vehicle as follows. Electric vehicles have a life of twenty years and their maintenance costs are five per cent. Petrol vehicles have a life of ten years and their maintenance costs are ten per cent. The 'fuel' costs of the latter are about four times greater than that of the former. The capital cost of the large electric vehicle is now lower than that of a petrol vehicle of similar loading capacity, and in addition the oil required is less and the tires last longer. The economic advantages, therefore, are in favour of the electric vehicle. The results show that the daily performance of an electric commercial vehicle after several years' use lies between 18 and 24 miles, and it can double this distance on one battery charge. Electrical vehicles are now available with speeds up to twenty miles per hour; but the radius can be extended by increasing the size of the battery. Increasing the size of the batteries is only advantageous when the batteries are in full-time use. Otherwise the heavier batteries mean additional non-paying load.

When the huge alternating current network of the Grid supply was completed, many thought that there would be little further use for storage batteries in connexion with lighting supply. Having practically obtained standardization, it is most unlikely that Great Britain will ever drift back into the large variety of voltages and systems of supply which existed before the advent of the Grid. There have been a few breakdowns and blackouts since the early years of its working, but their number is diminishing. In *Electrical Industries* of May 6, E. C. McKinnon raises the interesting point whether their number is not a secondary consideration to the question of the possibility of their ever occurring at all. The national supply is now so great that to consider emergency duplicates or alternatives for all of it is impracticable, but there are many sections of the community which might be imperilled in the absence of light and power. Statistics show that the list of installations where an alternative supply has been provided so as to be available in the remote possibility of the cutting off of the main supply by storm, riot, enemy's action, etc., is rapidly mounting. Engineers who have been studying the question of emergency plant recognize that there must be no appreciable time lost after a breakdown in putting it into commission.

It has been customary in the past to regard the average working life of a battery of the stationary type to be something over ten years. But this assumes that the battery has been working during this period. A battery that is only used for standby purposes has a much longer life. It is unlikely that any system of telephone supply would be run solely from the public mains. There is always a storage battery in reserve and so continuity of supply is assured. Proprietors of cinemas are compelled by law to instal a lighting supply secondary to the main supply.

The use of the storage battery as the nucleus for the alternative supply is now firmly established. In several hospitals the storage battery is introduced as a means of assuring constant illumination. The chances of interruption of the public supply are very small, but the outlay required to ensure an unfailing brilliant illumination by a storage battery with automatic control is not a serious item and might possibly save the life of a patient. In stores and public buildings the object of installing automatic emergency lighting devices is to prevent panic amongst those present and the prevention of pilfering should there be a breakdown of the main supply.

In central electric stations and electricity works standby batteries are much used to help carry over the peak loads and so delay the inevitable purchase of more generating plant. A large standby battery in a London supply station was kept fully charged by allowing a 'trickle' of current to flow continuously through it. When recently subjected to the annual examination it was found, for all intents and purposes, to be equal to new after nine years' running.

Turf Nurseries

THE experimental planting work carried out by Sir John Stirling Maxwell at Corrour in Inverness-shire over a long period of years has attained an almost, if not complete, world fame. It was a study of the Belgian system of turf planting which gave Sir John his first successes at Corrour. Since then he has inaugurated what may be considered a sound technique in afforestation work in this type of country.

Sir John has now applied the wide experience gained to the nursery. In the *Scottish Forestry Journal*, 50, Pt. 1 (Edinburgh, March 1936), he describes his method in an article entitled "Turf Nurseries". It is obvious, says the author, that the method has a restricted application; it can only be practised where peat beds are available. The method was suggested by the ease with which it was found possible to move trees planted on upturned turfs for several years after planting. The method is described as follows by the author:

"An area of peat is selected free from roots and boulders. Nothing is more suitable than the *Molinia* flats which are found on nearly all Scots moors. Turfs are lifted and turned over in continuous rows, leaving a space between the trenches from which they are taken just wide enough to carry the line of upturned turfs. These nurseries are best prepared in the autumn and planted in the spring, but this is not essential. The plants are inserted in the centre of each turf, a plug being cut out by a circular spade. A dressing of manure mixed with sand or gravel is applied to the roots of each plant. The plug is broken up and used to fill up the hole. Well-grown 2-year seedlings are the best plants for the purpose. As regards species, we have hitherto only used Sitka and Norway spruce and *Contorta* pine, but Japanese larch, which grows well on certain types of peat, should be equally suitable. As regards the size of nurseries, the ideal arrangement would be to have each nursery just large enough to plant an acre so that no plants would have to be carried more than thirty yards. In practice we have generally found it more convenient to make the nurseries rather larger, since the number of suitable sites is limited. After two years' growth in the nursery the plants are ready to move. They are carried on hand barrows, six or eight turfs to a barrow. Enough plants are left in position to make the nursery part of the wood. For Sitka we leave every fifth plant in every other row. For Norway every fourth plant. The remainder are set out at whatever distance is desired. If the heather is long a space has to be cut or pulled for each turf. Sometimes on very steep slopes it is necessary to make a nick to prevent the turf sliding downhill. The setting out is usually done as soon as the second year's growth is complete. It may be asked why the turfs are not cut where required and placed at once in their permanent positions. The answer is that there is great economy in concentrating all the preparatory work in one spot. Also the turfs are heavy to handle when first cut, whereas after two years' exposure they become much lighter."

Sir John states that the advantage of the system is that the plants receive no check at any stage in their growth; that the method can be used with success on ground where planting in pits or notching would result in prolonged check; and finally, where draining is required, it does not make up for the lack of it. The author discusses the types of countryside on which he thinks the method is applicable. He says that the turf nurseries require little shelter. Nurseries placed on exposed salients at 1,600 ft. in Scotland have produced plants which "would do credit to any lowland nursery". As regards manures, the old Belgian recipe of one part of slag to seven of sand has given the best results.

Sir John is modest, and thinks the scope of the method is limited. This is by no means so certain. There are parts of the Empire, by no means restricted to peat lands, where it is possible that this type of nursery rearing of plants might be applicable both with success and cheapness.

Educational Topics and Events

CAMBRIDGE.—Applications for a John Lucas Walker studentship in pathology are invited and should be sent before September 30 to Prof. H. R. Dean at the Department of Pathology, to whom requests for further information regarding the studentship may be addressed. This studentship will be tenable for such period and will be of such annual value not exceeding £200 as the professor of pathology with the approval of the Managers may determine.

The Board of Management of the Frank Edward Elmore Fund will shortly proceed to the award of not more than three or four studentships for research. The studentships are open to male graduates of any University in any country who were born at any place within the British Empire other than Scotland. The students first appointed will work in the Department of Medicine under the direction of the regius professor of physic. The commencing salary will be £300 a year.

At Clare College, Prof. R. S. Hutton, Goldsmiths' professor of metallurgy, has been elected into a professorial fellowship.

At Emmanuel College, the external studentship offered to graduates of other universities intending to commence residence as research students in October next has been awarded to C. O. Hutton of Otago University, New Zealand, for research in geology.

SCIENTIFIC research is made self-propagating by the peculiar methods in use by the Wisconsin Alumni Research Foundation. As explained in "A Decade of Service" recording achievements of the first ten years, 1925–35, of the Foundation's existence, this trust started with no invested capital but only a patent application belonging to one of the University professors, Dr. Harry Steenbock. The application, then pending before the United States Patent Office, related to the use of ultra-violet rays to enrich the vitamin D content of foods and medicinal products. A corporation was formed to exploit this patent and any others that might be similarly acquired from members of the University. In ten years the earnings of the Steenbock patent alone have enriched the University by nearly 700,000 dollars and provided an endowment worth more than 125,000 dollars a year for the future needs of research.

Science News a Century Ago

Use of Coal in American Steam-boats

ACCORDING to Admiral Preble, up to the year 1834, steam-boats in the United States burnt wood only. On August 18, 1836, *The Times* published a note from the *New York Evening Star* about the steam-boat *Novelty*, which said that "recent successful experiments of driving this boat, of the largest class, with anthracite coal, against the tide and a strong current at 16 miles an hour has caused much remark in the city, as an astonishing fact of great importance on the subject of fuel which may lead to revolutions in steam navigation. Dr. Knott, the distinguished president of Union College, is the proprietor of the *Novelty*, which he constructed, we believe, with machinery after his own ingenious invention. The fact of the practicability of using anthracite being now ascertained so as to produce as great a degree of heat as pine-wood, will no longer compel steam-boat proprietors to import their wood at exorbitant prices from the remote forests of Maine and the shores of the Chesapeake. Nearby, and almost at our doors, we have the anthracite coal mines of Pennsylvania, of every possible variety, in exhaustless quantities. The successful navigation of the Atlantic from America to Europe is made certain. Wood is now selling at the Hudson, at five or six dollars a cord. The cost, in fact, of pine-wood is about double that of anthracite."

Progress of Ballooning

IN 1836, balloon ascents were very frequent, and considerable sums were paid by passengers desiring to make an aerial voyage. The subject was one of great public interest, and on August 18, 1836, *The Times* in an article on "Aerostation" gave a chronological account of some of the landmarks in ballooning. In this article it said on September 19, 1736, J. Montgolfier sent up a balloon in Paris, filled in eleven minutes with the smoke of burnt straw and wool. Montgolfier then made a balloon of spherical form 45 feet in diameter and 75 feet high in which Pilatre de Rozier ascended, he having the honour of being the first aeronaut. On December 1, 1783, a balloon filled with hydrogen gas took up aeronauts in the persons of MM. Charles and Robert. In 1784 Madame Thible ascended at Lyons before the King of Sweden. She was the first aeronaute. On June 18, 1786, Mr. Festin ascended from Paris, and remained a whole night in the sky. On November 25, 1783, the first ascent in England was made by Count Zambecarri, from the Woolwich Artillery ground. He descended at Petworth. On September 21, 1784, the Chevalier Lunardi made the first ascent from London. On January 7, 1785, Mr. Blanchard and Dr. Jeffries, an American physician, ascended at Dover and descended near Calais. After referring to the use of balloons in military operations, the article concluded with the observation that balloons have not justified the expectations they raised.

Death of Edward Turner Bennett

ON August 21, 1836, Edward Turner Bennett, secretary of the Zoological Society, died at the early age of thirty-nine years. Born at Hackney on January 6, 1797, he was trained as a surgeon, and practised for several years near Portman Square. He devoted himself with the greatest ardour to the study of zoology. He took an active part in forming an entomological society and the Zoological Society. Of the latter he was at first vice-secretary, and from 1831 until his death the secretary. He contributed many papers to the *Transactions of the Zoological Society* and published "The Tower Menagerie" (1829) and the "Gardens and Menagerie of the Zoological Society" (1831). He also prepared an edition of White's "Natural History of Selborne", with numerous notes, which was published after his death. "From the affability of his manners and general scientific and literary attainments," said one writer, "he was highly respected by a numerous circle of friends."

The British Association at Bristol

THE sixth meeting of the British Association took place at Bristol during the week August 22–27, 1836. The proceedings were fully dealt with in the *Athenæum*, which published several double numbers. On Thursday, August 18, the correspondent of the journal wrote : "There is every fair prospect that the meeting will rival that in Dublin, both in the number and the high scientific character of its members. . . . Upwards of 600 new members were enrolled up to Wednesday evening. . . . As far as can be at present foreseen, Geology and Mechanical Science are likely to be the most important Sections. Reports are current that the Rev. Mr. M'Gawley's discovery of the possibility of deriving a motive power from electromagnetism . . . has received a new and important extension which may make sad havoc with steam and railway speculation—but on this subject your readers will soon be able to judge for themselves". Writing again on August 20, the correspondent said that the General Committee had received a letter from the Marquis of Landsdowne expressing his regret that he would not be able to take the chair owing to the illness of his son, and the committee had therefore elected the Marquis of Northampton as vice-president. "It was gratifying," he added, "to observe that all traces of the temporary estrangement of Sir David Brewster from his colleagues on the Council had disappeared".

Societies and Academies

Dublin

Royal Irish Academy, June 22.

C. F. HUMPHRIES and W. E. FROST : The Chironomid fauna of the mosses of the River Liffey. Quantitative samples of mosses were taken from the River Liffey (Ireland) from two contrasting stations ; one where the water was acid and one where it was alkaline. The species of Chironomid larvæ found in the mosses were identified ; the Orthocladiariæ constitute more than ninety per cent of the fauna at both places. The larval Chironomidæ are equally abundant in the acid and alkaline waters, and show only minor qualitative differences. Some notes on the seasonal distribution are given. Four new types are described and figured.

ARTHUR HOLMES : New analyses of Tertiary igneous rocks (Antrim and Staffa). Pending the publication of certain investigations by Dr. F. Allison and the author, it was thought desirable to make available four new analyses of rocks, made in the course of that work. Three of these are from Co. Antrim, namely, rhyolite, Tardree Mountain ; olivine-dolerite, Portrush Sill ; and basalt, Giant's Causeway. The fourth is the olivine-basalt of Fingal's Cave, Staffa.

JOSEPH ALGAR : The synthesis of diflavonols. Diflavonols may be synthesized by treating dihydroxy-dichalkones, such as dibenzylidene-diacetoresorcinol, with aqueous alcoholic sodium hydroxide and hydrogen peroxide. In this manner the following have been prepared, with satisfactory yields :—diflavonol ; 4′.4″-dimethoxy-diflavonol ; 3′.4′-3″.4″-tetramethoxy-diflavonol ; 3′.4′-3″.4″-dimethylene-dioxy-diflavonol. Since dihydroxy-dichalkones are readily obtained from diacetoresorcinol and the suitable aldehyde, the reaction affords a convenient general method for the synthesis of diflavonols.

Brussels

Royal Academy (*Bull. Classe Sci.*, No. 4, 1936).

G. CESÀRO and J. MÉLON : On cryolite. Refractive index, birefringence perpendicular to various faces and crystalline forms.

J. E. VERSCHAFFELT : The thermo-mechanics of the surface layer. (1) Generalities. (2) The adsorption formula. (3) Mixed phases.

E. DE WILDEMAN and E. VERLEYEN : The budding of the epiphylous tissues in some monocotyledons.

M. DEHALU : Bernstein's theory relating to the hereditary probabilities of blood groups.

L. GODEAUX : Some involutions belonging to the generalized Humbert surface.

P. GÉRARD : The homology between the sense organs of the lateral system and those of the vestibular system in the teleosteans.

P. L. CATTALA : Photo-electric recording of the time of passage of stars. Preliminary theoretical study : variation of the luminous flux through a reticule at the passage of a stellar image.

R. CORDIER : The cutaneous sense organs of *Protopterus*.

G. VAN LERBERGHE and P. GLANSDORFF : Contribution to the thermodynamics of open systems.

E. ANGLADE : Flecnodal surfaces of a ruled surface.

L. DERWIDUÉ : Linear congruence of conics.

B. GAMBIER : Study of the cubic surfaces which can possess Eckardt points.

J. L. DESTOUCHES : Role of the notion of stability in physics.

L. MARTIN : Problems of the limits relative to certain systems of partial differential equations.

G. SOKOLOFF : Singular trajectories in the problem of three bodies which attract each other proportionally to their masses and to a function of the distance (2).

M. LECAT : Remark on the note entitled : "The logical foundations of the theory of probabilities", by S. Avsitidysky.

JEANNE HENRY-CORNET : Study of the absorption spectrum of bilirubin.

Cracow

Polish Academy of Science and Letters, May 4.

G. GIRAUD : A property of certain generalized logarithmic potentials.

J. WEYSSENHOFF and A. BIELECKI : Quaternions, rotations in space of four dimensions, and the formula of Cayley.

M. MIESOWICZ : The influence of the magnetic field on the viscosity of liquids in the nematic phase. A magnetic field produces a marked increase in the viscosity of *p*-azoxyanisol and *p*-azoxyphenetol in the nematic phase.

B. Kamienski and J. Inglot : (1) The dielectric potential and surface tension of cholic acid solutions with different concentrations of hydrogen ions. (2) The influence of the hydrogen ion concentration on the dielectric potential of a solution of potassium chloride.

K. Smolenski and W. Kozlowski : The rotatory power of alkaline solutions of saccharose.

Mlle. R. Ludwiczak and J. Suszko : Alloquinidine, a carbinol base derived from quinidine.

J. Suszko and M. Wdowicki : Naphthalylmalonic ether and peri-naphthindandiono-carboxylic acid.

K. Konior : The profile of the Dziedzice Pleistocene.

M. Ksiazkiewicz : The structure of the Lanckorona zone.

M. Mereminski : The development of the embryo-sac in *Begonia incana*. Contribution to the embryology of the genus *Begonia*.

S. Mikulski : The influence of alternating temperatures on the development of the eggs of batrachians : *Bufo americanus* and *Ambystoma tigrinum*.

J. Zacwilichowski : Researches on the innervation and the sensorial organs of the wings of *Isopteryx tripunctata*.

T. Garbowski : The repetition of instinctive acts generally done once only. Remarks on some experiments on Dicranura and Cerura approaching the chrysalis stage.

June 8.

G. Giraud : A generalization of logarithmic potentials of a double layer.

A. Jagielski : The dielectric polarization of the liquid chloronitrobenzenes.

S. Dobinski and J. Wesolowski : The density of liquid selenium. The density of selenium between 228° C. and 345° C. is a linear function of the temperature, and shows no sudden variations corresponding to those found by Pélabon in the electrical conductivity of this substance.

A. Ziemecki and K. Narkiewicz-Jodko : The continuity of the variation of the cosmic radiation in the upper layers of the troposphere. The results of G. A. Suchstorff were not confirmed, and the authors regard it as unlikely that radioactive bodies are present in the higher regions of the atmosphere.

M. Kamienski : Study of the motion of the Wolf I comet.

F. Kepinski : The movement of the periodic comet Kopff (1906 *e*).

K. Smolenski and S. Porejko : The *p*H of solutions of lime in water and in solutions of saccharose.

L. Marchlewski and Mlle. R. Grünbaum : Absorption of ultra-violet radiation by gossypol.

W. Goslawski : The influence of the hydrogen ion concentration on the dielectric potential and surface tension of solutions of cinchonine and cinchonidine.

J. Szaflarski : Remarks on the thermal properties, transparency and colour of the lakes of the south-west part of the High-Tatra massif.

Mlle. J. Dyakowska : The interglacial period at Poniemunie near Grodno.

T. Litynski : The estimation of nucleic phosphorus in the seeds of the bean, *Vicia Faba minor*.

Mme. W. Zablocka : The mycorrhiza in the genus *Viola*.

K. Rouppert : The leaf of *Philodendron squamiferum*.

J. Marolski and St. Smreczynski : The Coleoptera of the Pleistocene of Leki Dolne, near Pilzno.

F. Rogozinski and Zb. Glowczynski : The behaviour of some liposoluble colouring matters in the animal organism.

Research and Teaching in Universities

ONE of the most impressive passages in the recent report of the University Grants Committee is that in which attention is directed to the opportunity of service before the universities to-day in training the right type of leader, competent to think strenuously about great issues of right and wrong, liberty and government, and to bring to the grave problems of to-day minds richly informed and unsleeping in the exercise of critical intelligence, and imaginatively alive to the human issues underlying the decisions they are called upon to make. In an age when appeals to mass hysteria often appear to be more successful than appeals to reason, it is of the utmost importance that a university training should enhance a man's equipment not only as a skilled worker but also as a member of society and a human being.

The desirability of closer contact between the universities and the life of the community was also emphasized in speeches at the banquet on June 29 in connexion with the centenary celebrations of the University of London. Prof. L. Cazamian, of the University of Paris, referred to the function of the university in developing the unselfish love of peace, and a creative instinct of fair play to all the nations. The slow victory of a ripe spirit of justice over the promptings of blood, life and force is a subject for noble pride that something of the will to power of past ages might be sacrificed to a new hope and a new faith.

In a speech on the same occasion, Sir James Barrett directed attention to the value of a university as a place where a problem could be discussed without being overlaid by political and financial considerations. A university, however, cannot speak in the collective sense, and if a professor speaks individually he is apt to be criticized if his notions do not agree with those of some of his hearers. Sir James Barrett suggested that the function of universities as a whole to meet the crying need of a world in constant travail is the production of men with balanced minds, organized intelligence and common sense.

This plea that the universities should no longer be regarded as unco-ordinated centres of specialized knowledge, but should come into closer contact with social problems and give an enlightened lead to the community independently of political parties, has frequently been advocated in different ways during recent years. Essentially it involves two separate questions. The first is the impartial study of social and economic questions, as has been carried out in recent years by the Research Section of the Department of Economics and Commerce at the University of Manchester under the leadership of Mr. John Jewkes. The second is the training of leaders for the community who possess the vision and personality to compel action along the lines indicated as a result of such investigations.

In regard to the first, Sir James Barrett suggested that some system of interlinked university research throughout the world, on the lines of that developed internally in the Commonwealth of Australia under the Council of Scientific and Industrial Research, is required. Without an educated public, however, it is almost impossible to ensure that the results of such investigations are fully utilized for the advantage of the community.

The problem is thus one of education and teaching as well as research or investigation, and the question of the right relation between teaching and research in the universities is one of the most important of those raised by the recent report of the University Grants Committee. It has since been discussed in a valuable article by Dr. R. Coulborn in the *Nineteenth Century*, and reference was made to the same problem by the Prime Minister in opening the fifth Congress of Universities of the British Empire at Cambridge on July 14.

Unquestionably one of our first needs is the re-orientation of research at the universities, and the institution of research in the biological sciences and the humanities, so that we may be in a better position to deal with the many social problems with which the unparalleled and disproportioned development of the physical sciences has confronted us. In such work the prime need is for creative research, and Dr. Coulborn does well to remind us that much research work can be, and is, undertaken without any preceding act of creation. In fact, the patience, dexterity and precision demanded in so much research to-day tend to blunt the enthusiasm, imagination or vision of the investigator. He tends to become a machine, and cannot easily escape some warping of his mind or loss of humanity.

These effects of specialization cause the research worker to lose interest in teaching, and it is for this reason rather than to free the investigator from other distractions, as Mr. Baldwin suggests, that some reconsideration of the close connexion between research and teaching which at present exists in the universities is desirable. Undoubtedly it is true that the investigator of genius, the man with really creative ability, should be free from other claims on his time so far as possible. It is equally true that he is likely to be lacking in the patience which research demands, and will require a number of other workers to carry out the detailed work along the lines his genius suggests. It may also be true that his creative ability will be combined with a capacity for inspiring enthusiasm in others and thus for some measure of teaching, which is the fundamental reason for believing that the university teacher should himself be engaged in original work in his subject.

Such men, however, will always be the exceptions, and Dr. Coulborn's warning as to the damaging effects of research in university education cannot be lightly disregarded. He considers that the numbing influence of research on character destroys the teacher's ability to interest and inspire, while undergraduate studies are also usually planned on a basis of progressive narrowing down towards research minutiæ instead of being such as to offer the student the deepest understanding of his subject. If we accept the view urged by Mr. C. H. A. Wilson, vice-chancellor of the University of Cambridge at the recent Universities Congress, that the universities are national and imperial institutions, and that it is their duty to train against a background of pure scholarship men and women who are fitted to take a lead, or at any rate a creditable part, in the conduct of social, commercial and political administration, the question of the quality of the teaching given acquires primary importance.

The evidence cited by Dr. Coulborn suggests that our present practice of linking teaching and research is inefficient even from the point of view of research, and that much superior results would be obtained if the functions of research and teaching were entirely separated and made full-time occupations. Not only is it probable that teaching would be more effective and inspiring and more adapted to the social needs of the student if such a division were effected, but also it would be easier in the transition to secure a re-orientation and direction of academic research in the fields in which it is most demanded by the needs of the community. Moreover, a check would be given to that untoward tendency for undergraduate training to approximate to a soul-destroying professional training instead of the training in scholarship, in strength of character, and in potentialities of good citizenship, which it should be the glory of a university to give as a preliminary foundation of professional training.

There need be no fear that such a separation of functions would lead to any debasement of research. On the contrary, it is more likely to enhance its repute if the conduct of research is a full-time activity of investigators appointed for the purpose rather than the part-time activity of a lecturer or an aspirant for a higher degree. The prestige of research could only be enhanced by being placed on a footing which would enable its real leaders and men of genius to direct and inspire the large army of patient investigators whose co-operation is so essential in any advance to-day.

One of the most important consequences of such a separation of functions would equally be the encouragement which could be given to the really great teacher with a genuine talent for exposition and inspiring others. Such teachers, though teaching may be their whole occupation, will never fail of that constant refreshment at the fountain heads of knowledge which is essential if their teaching is to retain its freshness and vitality. The present interrelation of research and teaching, in fact, has few more untoward consequences than the way in which it tends to diminish the prestige or status of such expositors who, whether within the walls of a university or in the nation at large, are one of the greatest needs to-day. Only through the work of sincere, able and fearless expositors can we hope that either the alumni of our universities will awake to the vastness of their opportunities of leadership and constructive service in the world to-day, or humanity at large realize how great are the benefits which the acceptance of such leadership could confer upon them. The separation of teaching from research in such ways as these may well advance the dignity of both, and enable the universities to make an ever-growing contribution to our national and imperial well-being. This service will be rendered alike through the provision of exact and impartial knowledge and analysis of the factors concerned in many of our grave social or economic problems to-day, and in the training and inspiring of those who can bring to bear upon them constructive criticism, moral courage, a wide vision and a keen sense of human values.

Native Agriculture in Africa and its Relationship to Population

The Improvement of Native Agriculture in relation to Population and Public Health

By Sir A. Daniel Hall. (University of London: Heath Clark Lectures, 1935, delivered at the London School of Hygiene and Tropical Medicine.) Pp. vii+104. (London: Oxford University Press, 1936.) 10*s*. 6*d*. net.

IN this book, Sir Daniel Hall deals with some of the many problems which have arisen from the impact of modern civilization on the native tribes of Africa. The increase in the human population and in the number of cattle which followed the stoppage of war and the reduction in epidemic disease has led to a dangerous condition—"The eminent consequences are disease due to inadequate diet, tribal unrest and the spread of the desert".

Primitive native agriculture is carried on by the method of 'shifting cultivation'. A piece of bush or forest is burned, and the ashes scattered. On this virgin soil crops are grown for one or two years, by which time the land is overrun by weeds. It is easier to burn another area than clear the weeds and fertilize the soil, so a further area of primitive jungle or forest is burned. So long as the population was small, Nature could repair the damage at leisure. But the population has increased to such an extent that regeneration no longer keeps pace with destruction. Apart from the increase in the population, the process of destruction is increasing owing to the growing of cotton and other products by the native for sale.

To the destruction of the land by the natives there is added the destruction by domestic animals. The increase in the number of cattle, sheep and goats has upset the balance between the grazing animal and the pasture. The pasture gets eaten down to the very roots, and even the roots are destroyed by the goats. On the slopes, the tropical rain washes away the top fertile soil, no longer bound by the mat of vegetation. There results an area completely denuded of vegetation. In this way the desert is steadily spreading. This is a problem which is not confined to East Africa. Soil erosion due to over-stocking has become a most serious problem in various parts of the world.

Unfortunately, the native will not sell his cattle. The wealth and prestige of the family and the tribe depend upon the number of cattle, and the possession of cattle is interwoven with the social and religious structure of native life. Cattle, sheep and goats are, to the African native, even more important than money is to the modern European. Immense numbers are kept quite independently of their value for food or any useful purpose, except the maintenance of wealth and prestige. It will be exceedingly difficult to demonetize cattle in East Africa.

Associated with the problem of the growing population with decreased fertility of soil, is the widespread occurrence of malnutrition. Inadequate diet is one "if not the chief source of disease among African natives". If the health of the native is to be improved, the improvement must begin with better food.

After reviewing the present conditions and showing how they have arisen, the author in the final chapter suggests what should be done to prevent "famine and the spread of desert" replacing war and pestilence, as a means of reducing the population. The essentials of a new system are: "(1) the replacement of shifting cultivation by a fixed agriculture which will maintain continuous production from a smaller area, leading to a more balanced dietary; (2) the elimination of excessive live stock and the utilization of the remainder to provide food; (3) the prevention of soil erosion and the reconditioning of the devastated areas".

Sir Daniel Hall has brought to bear on this problem of East Africa his great fund of biological scientific knowledge, and his long administrative experience. The results of his study given in this book are an interesting illustration of the value of approaching political and economic problems from the point of view of the man of science, who is accustomed to dealing with ascertained facts rather than preconceived political ideas.

This book should be read not only by those who are interested in the great problem of the native races of Africa, but also by those interested in the application of science to present-day world-wide problems of economics.

J. B. Orr.

Concentrated Solutions

Les solutions concentrées: théorie et applications aux mélanges binaires de composés organiques. Par Prof. Jean Timmermann. Pp. vi + 646. (Paris: Masson et Cie, 1936.) n.p.

Fifty years ago, important advances were made when Arrhenius and van't Hoff made their classical studies on the conductivity and osmotic pressure of aqueous solutions; but the rules which they established were valid only for dilute solutions, and in most cases were rigidly true only at dilutions at the extreme end of the range, where the percentage of the solute is only a very minute fraction of the whole. Prof. Timmermann's book, on the other hand, is concerned with those solutions in which the two components are present in comparable quantities. Its scope is indicated by the exclusion of all systems for which there are no data between 10 and 90 gm. per cent, or only one datum between 10–20 per cent or 80–90 per cent. A sub-title also restricts the book to "theory, and applications to *binary* mixtures of *organic* compounds".

Even with this limitation, the data occupy a volume of 600 pages, which is illustrated by a series of 540 figures, many of which include more than one property in the same figure. The book is, however, by no means a mere dictionary, since it begins very happily with a fascinating account of the admixture of compounds the molecules of which are mirror images of one another. Seven diagrams show the freezing points of mixtures of *d*- and *l*-forms of various optically active compounds, some of which (for example, methyl tartrate and butyl phthalate) form a crystalline racemate with a higher melting point than either of the active components, whilst others (for example, phenylglycollic acid) form a less stable racemate of lower melting point. In other cases again, the *d*- and *l*-forms are isomorphous, and yield 'solid solutions' in all proportions, as in the remarkable case of *d*- and *l*-camphoroxime, or within narrower limits of miscibility. The difficult question of the existence or persistence of racemic compounds in the liquid state is answered in the affirmative in certain instances by a study of the experimental data now cited.

The second chapter of the book extends this study to mixtures of *isomers* which are not mirror images of one another, but differ either in configuration (stereoisomers) or in constitution, and of *polymers* which differ also in molecular weight. In this series of mixtures a clear distinction is drawn between (*a*) *static isomers* (or polymers) where, in spite of their identity of composition, each component is a stable well-defined compound, yielding true solutions when mixed, such as propionaldehyde and acetone, or acetylene and benzene; (*b*) *dynamic isomers* (or polymers) which behave as static isomers in the absence of a catalyst, or in presence of a negative catalyst, but undergo reversible change in presence of a positive catalyst, such as acetaldehyde and paraldehyde in presence of sulphuric acid; (*c*) *tautomers*, to which more than one molecular structure can be assigned, but which are too mobile to be separated into two constituents, such as (i) 1:2 and 1:6 dichlorobenzene, or (ii) stereoisomers which are interconvertible by free rotation about a single bond. Examples which are cited of the group of interconvertible isomers include (i) the dichloroacetylenes studied by Chavanne (and seven other pairs of olefines) which are interconvertible when pure, but can be stabilized by the addition of alcohol, (ii) ten pairs of interconvertible stereoisomers, including two pairs of oximes and the classical examples of fumaric and maleic acids, (iii) acetaldehyde and paraldehyde, (iv) ammonium sulphocyanide and thiourea, studied in very full detail by Werner in Dublin.

In the third chapter of the book, the compounds which are mixed need not be identical in composition, provided that they are sufficiently similar to form isomorphous mixtures. In this field the author (following Bruni) has himself done important work. Thus, in spite of free rotation in the liquid state, ethylene dichloride (I) evidently takes up preferentially a *trans*-configuration, since it forms mixed crystals with the *trans*-form II of dichloroethylene, but a eutectic with the *cis*-form III of this compound, the configurations of which are fixed by the presence of a double bond.

I.  $\begin{array}{c}CH_2Cl\\ |\\ CH_2Cl\end{array}$

II.  $\begin{array}{c}Cl{\cdot}C{\cdot}H\\ \|\\ H{\cdot}C{\cdot}Cl\end{array}$

III.  $\begin{array}{c}Cl{\cdot}C{\cdot}H\\ \|\\ Cl{\cdot}C{\cdot}H\end{array}$

IV.  $\begin{array}{c}CHCl_2\\ |\\ CHCl_2\end{array}$

On the other hand, he has discovered, *inter alia*, that ethylene dichloride (I) forms an equimolecular compound with the symmetrical form of the tetrachloro-compound, IV. The formation of equimolecular aggregates of this type is attributed to the preferential packing of complementary molecules of I and IV, in just the same way that an equimolecular mixture of *d*- and *l*-tartaric acids forms a more stable aggregate than either type of molecule separately. In order to recall this analogy, the equimolecular mixtures are described as "racemoids".

The fourth chapter of the book deals with mixtures of substances of similar type, for example, homologous hydrocarbons, alcohols, esters and amines, substitution products such as $C_2H_4Cl_2$ and $C_2H_2Cl_4$ or *di*- and *tri*-nitrotoluene, and mixtures of compounds with unequal numbers of aromatic rings, such as the binary mixtures formed by benzene, naphthalene and anthracene.

In the preceding systems, which form Part 1 of the book, analogy of structure between the components often produces simple relations in the physical properties of the mixtures, although this is very far from being universally true. Part 2, on the other hand, deals with components of different chemical types, and Part 3 with systems in which one of the components includes a hydroxyl group. The relationships are now more complicated, and long tables are given of mixtures which are 'azeotropic', because they form mixtures of minimum (or more rarely, maximum) boiling point. (The introduction of the term by Wade and Merrimann in 1911 is cited on p. 159.) Shorter lists are also given of pairs of substances which yield two liquid layers at temperatures below the 'critical solution temperature'. Even in these more complicated sections, however, the book never reverts to the status of a mere catalogue, since the reader will find various special subjects, such as the influence of solvents on optical rotatory power, or the behaviour of systems containing anisotropic liquids, adequately discussed, with diagrams and references to the original literature.

The bibliography at the end of the book covers 26 pages, papers published in the same year being given a serial letter, for example, 1914 *b*, which (with the date) suffices to define the reference. The mixtures are indexed in the sequence of formulæ used in Richter's "Lexicon", beginning with methane, CH_4, and ending with tristearine, $C_{57}H_{110}O_6$, the component with the simpler formula in Richter's sequence being chosen for the primary entry in the index. The second component of the mixture is then indexed in the same sequence under the first component. Since the formula of each component is accompanied by the name of the compound in question, isomers are always grouped together but are clearly distinguished from one another.

The book as a whole is a monument to the patience and skill of the author, who has rendered a real service to his colleagues by undertaking so formidable a task for their benefit. T. M. L.

A New 'Oxford Atlas'

The Oxford Advanced Atlas
By John Bartholomew. Fifth edition. Pp. iv+96+32. (London: Oxford University Press, 1936.) 10*s*. 6*d*. net.

THE outstanding feature of the new "Oxford Advanced Atlas" is a larger page with larger maps. This has allowed of the introduction of double-page maps of the Iberian Peninsula and the Balkan States. With their inclusion, the atlas now shows the whole of Western, Central, and Mediterranean Europe on the 1 : 3,000,000 scale. There are also new double-page maps of the U.S.S.R., South-West Asia, the Malay Archipelago, the Laurentic Basin, Central and East Africa, and South Africa.

The atlas is thoroughly up-to-date. The "Sarre" of previous editions has become the "Saar", with the former northern and eastern frontier lines deleted. The new and highly significant railway links between Polish Silesia and Gdynia are shown, and British coal exporters as well as Danzig shippers are likely to be affected by them. The map of the Soviet Union is especially useful, since it emphasizes the essential unity of the European and Asiatic territories of Russia, and their relationship to the marginal lands of Mongolia and Manchukuo. Moreover, it is now possible to locate much-advertised names like Gorki, Dnieprostroy, and Magnitogorsk.

Mercator's projection has been banished from the atlas, except in an illustration on the pages devoted to map projections in general, and the atlas now lacks a serviceable map of world shipping routes. The world political and population maps are drawn on a new equal-area projection termed the Re-Centred Sinusoidal. This shows the land areas true to scale with a minimum of distortion. There is also a valuable map on the morphology of Europe, embodying a more precise classification of the relief features (on the basis of structure) than has hitherto obtained.

In the case of the British Isles, what are described as "the rather elementary county-coloured maps of the earlier editions" have been omitted. One result is that the atlas lacks a satisfactory map of the counties of the British Isles, which seems a pity in view of our strongly developed territorial sense. Another result is that many places found in previous editions do not occur in the present one. To give a test case—the fourth edition marks nineteen places in Hampshire and the Isle of Wight which do not occur in the present edition. It would be ungracious, however, to labour this deficiency in view of the full measure provided elsewhere in this beautifully produced atlas. The claim of the publishers that it should prove "well-nigh indispensable to all who wish to take an intelligent interest in the world they live in" is justified. It definitely supersedes previous editions.

Fish and Fishing

(1) Letters to a Salmon Fisher's Sons

By A. H. Chaytor. Fourth edition. Pp. xxviii + 316 + 8 plates. (London: John Murray, 1936.) 9*s*. net.

(2) Sea Trout and Trout

By W. J. M. Menzies. Pp. 230 + 16 plates. (London: Edward Arnold and Co., 1936.) 10*s*. 6*d*. net.

(3) Trout Heresy

By P. B. M. Allan. Pp. 206. (London: Philip Allan and Co., Ltd., 1936.) 8*s*. 6*d*. net.

(1) SINCE the publication of the third edition of this well-known book, the author has died. It is, as its title suggests, in the form of a series of letters from an ardent salmon fisher to his sons. Presented in this way the information is simply, although adequately, set forth, and it is possible that the author's legal training has a great deal to do with the clarity with which he makes his points. It is evidently the result of long experience, and written in a manner that can be read by the beginner and more experienced angler with equal profit and enjoyment. The present edition is prefaced with a short sketch of the author by Mr. A. Drewett Chaytor, one of the sons for whom the letters were originally written.

(2) Mr. Menzies, the author of "Sea Trout and Trout" is particularly well qualified for his task. As inspector of salmon (including trout) fisheries for Scotland, he has access to the literature of the many researches that have been conducted in this field. During the past fifteen years a great deal has been done in various countries, but particularly in Scotland, to extend our knowledge of the life-history and habits of the trout, and in this work the author has taken a prominent part. In addition, he is an enthusiastic fisherman with an exceptionally wide knowledge of all the Scottish waters. Thus in telling his story he is able to utilize the most recent information to illustrate those points in which the ordinary naturalist and the angler are interested, and he has achieved considerable success.

The modern view is that sea-trout and trout are simply the migratory and non-migratory races of the same species. After some general chapters the book passes on to the life-history of the two races, from the spawning in the redd, through the smolt, whitling and kelt to the old fish again, and the various problems connected with each of them are succinctly dealt with. Such problems include the determination of age from the scales, the food, the results of marking experiments and the seasonal movements. The concluding chapters treat of diseases, abnormalities, parasites, homing instinct and the making and preserving of a sea-trout fishery.

The book is furnished with an index and a short but useful bibliography; it is well illustrated and printed. The straightforward manner in which it is written should give it a wide appeal.

(3) This volume approaches the problem of fishing from yet another point of view, for the first treats of the art of catching fish, the second of the science of their lives and the third of the psychology of the fish and, by inference, that of the fisherman. The author examines the physical

and more particularly the mental equipment of the trout, its senses and their modes of action. This is done in the light of comparative psychology to a considerable extent, but also in the light of a great deal of actual observation by the author and other experienced anglers.

Certain writers tend to endow the trout with almost superhuman attributes, an attitude explained thus: "The rest of the truth is that be we never so skilful, boast we half a century of experience, we can catch trout but little more easily —if at all—than when we were striplings. There *must* be something in it—quite obviously trout are extremely cunning fish." A quotation from such a eulogy serves as an excellent Aunt Sally to be knocked down by the author with considerable gusto. What are the parts played by instinct and intelligence in this cunning? Can the fish profit by experience? Why do they rise? To what extent are they capable of distinguishing flies or other bait? Why are there often two types of trout in the same water? These and other problems that have been pondered by fishermen since first a fly was cast or a minnow spun, are treated in an engaging manner which never becomes tedious or didactic, although the opinions put forward are well documented by footnotes. The pure dry-fly man comes in for some delightful gibes, but they are always kindly and never sneering. It is just the book for the fisherman to take with him on his trip, for he will find in it much food for thought and new side-lights on old problems.

Review of Biochemistry

Handbuch der Biochemie des Menschen und der Tiere

Herausgegeben von Prof. Dr. Carl Oppenheimer. Zweite Auflage. Ergänzungswerk, Band 3. Pp. xxiv+1162. (Jena: Gustav Fischer, 1936.) 84 gold marks.

IN previous reviews of this Brobdingnagian offspring (see NATURE, 133, 595; 1934; and 135, 287; 1935) we have already commented on its dimensions and the deducible dimensions of its parent. In this third volume of the "Erganzungswerk" to the second edition of the "Handbuch" we have 1,136 pages of text and 25 pages of index, giving a total almost identical with that of the first volume; this was, however, published in two half-volumes of about 600 pages each, and there is no clue to the reason for the production of this monster between a single pair of covers.

This third volume is supplementary to vols. 7–9 (Parts 8–10) of the main volume. It covers metabolism under special conditions, including the processes of birds, cold-blooded animals, and invertebrates; metabolism under physiological conditions, including growth, pregnancy, heavy labour, hunger and under-nutrition, variations of climate, and radiation; metabolism under the influence of secretions and of endocrine disturbances; metabolism under various pathological conditions, including fevers, nervous disturbances and deficiency diseases; and the metabolism of the female generative system. These various sections constitute the supplementary material to Part 8 of the main volume.

The supplementary material to Part 9 is concerned chiefly with the metabolism of particular organs and tissues, including tumour tissue, and with the metabolism of the various essential food constituents, water, minerals, carbohydrates, proteins, creatine and creatinine, nucleides, fats and lipoids. Part 10 is supplemented by a survey of all those subjects that are comprised under the general phrase "Regulation of Function"—including both non-specific (for example, nervous) and specific regulation, as by vitamins and hormones. The section here on the biochemistry of the sexual hormones is, incidentally, described in a note as itself supplementing Dr. Butenandt's contribution to the first supplementary volume, published in 1933—a clear demonstration of the exceptionally rapid progress now being made in the field. Separate sections in the supplement to Part 10 are devoted to the physiology of the various endocrine organs. Finally, there is a useful addendum on the sterols, bile acids, and inositol.

As in the previous supplementary volumes, the names of many of the contributors are biochemical household words. Avon, Krüger, Lehmann, Pincussen, Felix, Fürth, Grafe are among the professorial contributors, supported by a number of *Privat-Dozenten* to a total of some twenty. This volume completes the task of supplementing the "Handbuch's" second edition. It maintains the authoritative character of the other two volumes and constitutes with them a quite indispensable whole.

Words almost fail one at the scope and completeness of the "Handbuch" and the supplementary volumes. If a reviewer may be permitted to repeat himself, it can once more be stated that "these volumes are of the kind that fill the user with awe-inspired gratitude and the reviewer with awe-inspired terror". A. L. BACHARACH.

A Pilgrim's Quest for the Divine

By Lord Conway of Allington. Pp. 255. (London: Frederick Muller, Ltd., 1936.) 10*s.* 6*d.* net.

LORD CONWAY's book reminds one of a philosophical romance such as "Rasselas", or even "John Inglesant". Much of it is in dialogue, and the scene passes from place to place—Switzerland, Italy, the Andes, Spitsbergen. The writer has been a pilgrim in the physical as well as in the spiritual sense. This is not a systematic treatise; but readers can go on with interest, and take the ideas as they come—they are always suggestive and often ingenious. Not that it is a casual book, for it has been rewritten four times, the author tells us, and he is working out his point of view all the while.

The problem with which the book is largely concerned is that of time and its relation to eternity, especially in the light of the theory that time is a fourth dimension of space. Lord Conway asks whether this conception may not "involve an entire revolution in our ideas about both the present and a possible so-called future life". His theory is that we are living and active in a three-dimensional state which exists within a four-dimensional universe. As we pass through the latter (as a two-dimensional inhabitant of Flat-land might pass through our three-dimensional world), "we leave behind us in what we regard as the passage of time the result of our actions built into the structure of our lives". This enables Lord Conway to envisage something in the nature of the Pauline conception of a "spiritual body", built up by a life's activities much in the way that a crystal is built up.

The last pages of the book consist of extracts from a diary kept by the author while staying with a small Franciscan community on an island near Venice. These are of particular interest, and the author seems to plead for something in the nature of a modern Third Order of St. Francis.

> "After all, St. Francis was not a mere visionary but a practical reformer. Why should not practical men of our day take up his work in a new form suitable for our present needs? Has not the passion for worm-eaten speculation yet made victims enough?"

The reader must come to this somewhat unconventional book with a sympathetic mind; but if he does so, he will find it very fruitful, even fascinating.

J. C. H.

Bibliographia Coleopterologica

Pp. xv + 149–323. (Den Haag: W. Junk, 1935.) 10*s.*

THIS publication is a special cloth-bound catalogue issued by the well-known entomological publisher, Herr W. Junk, now of The Hague. While, in principle, it is a priced list of books, reprints and journals, bearing, in the main, upon insects of the order Coleoptera, in reality it serves a much wider purpose. It is, in fact, a partial bibliography of the order, which is accompanied by a most useful index, so arranged with cross-references that publications on practically every aspect of the order can be readily found. It is intended also to serve the purpose of marking the jubilee of Herr Junk's most famous publication, the "Coleopterorum Catalogus", which was begun in the year 1910.

An interesting preface by S. Schenkling discusses the origin, history and purpose of this great work. The "Catalogus", which is now nearing completion, is the largest single work ever published dealing with the literature of any section of biology. It lists all the described species of beetles of the world, and the 141 parts (in twenty-one volumes), published to date, comprise 21,000 pages, containing the names, synonymy, distribution and taxonomic and biological literature of some 175,666 species. When completed, it will be comprised in thirty volumes, listing about 240,000 species in 134 families. The necessity for a reference work of this kind is borne out by the fact that its precursor—the Catalogue of Gimminger and Harold (1868–1876)—listed only 77,000 species.

A Comprehensive Treatise on Inorganic and Theoretical Chemistry

By Dr. J. W. Mellor. Vol. 15: Ni, Ru, Rh, Pd, Os, Ir. Pp. viii + 816. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1936.) 63*s.* net.

VOL. 15 of "Mellor" includes nickel and five out of six elements of the platinum group. Only platinum itself remains, with a general index, to complete the final volume, which is described as "in the press". As the author's huge task approaches completion, the admiration called forth by its monumental character increases to a climax. For example, the reviewer was surprised to find his own name cited under nickel as joint author of a paper in which he himself had forgotten that this element was investigated. Such a thorough scouring of the literature can leave very few gaps to be filled up, and provides a wonderful guide to all the work done up to the date of compilation of the volume in question.

As in previous volumes, the dictionary aspect is relieved by occasional discussions, for example, on the atomic weight and valency of osmium, with special reference to the formulation of the tetroxide.

At this stage, no further commendation is needed, since in a short time the present notice will give place to congratulations when the final volume appears.

Einführung in die angewandte Akustik:

insbesondere in die neueren Probleme der Schallmessung, Schallübertragung und Schallaufzeichnung. Von Dr. H. J. von Braunmühl und Walter Weber. Pp. v + 216. (Leipzig: S. Hirzel, 1936.) 9.20 gold marks.

FROM the physics point of view, this text is admirable. It covers most of the important applications of acoustics in the field of electrical communication, amongst which may be mentioned the measurement of performance of loudspeakers and microphones, the recording and reproduction of sound in its varied forms, acoustic perspective and the technical acoustics of enclosures. The last chapter appropriately deals with the measurement of fidelity of speech in communication systems, but the more difficult problem of measuring the fidelity in musical reproduction is not discussed.

Polarization of Light and some Technical Applications

By Prof. A. F. C. Pollard

WHATEVER may be the nature of light, it is convenient to regard it as the propagation of an electro-magnetic disturbance in the ether. In an isotropic medium, free of electric charge, the electric and magnetic vectors are perpendicular to one another and to the direction of propagation. Either of these may be selected as the periodic vector—the light vector—associated with the disturbance, but it is usual to define the plane of polarization as that containing the magnetic force with the electric force perpendicular to it.

There are three fundamental qualities which are of major importance to the control of light. The wave-length, which determines the frequency or colour and the amplitude upon which the intensity of light depends, are two of these qualities which have been under almost unlimited control for centuries. But the third—the direction and type of the transverse vibration—has continued to be under very limited control up to the present time only since 1669 when Erasmus Bartholinus observed the double-refraction of Iceland spar. A few years after the publication of Bartholinus's work, Huyghens indicated the distinctive character of the two beams transmitted by the spar, and Newton's discussion on the two-sidedness of the beams led to their subsequent description as polarized light. Curiously enough, this great discovery lay dormant as an isolated fact in science until about 1808, when Malus accidentally observed that the light reflected from the glass windows of the Luxembourg palace in Paris was polarized. Biot, making use of Malus's discovery, constructed his reflecting polariscope, which was one of the first devices to produce polarized light somewhat inefficiently by reflection.

It was not until 1828, however, that the optical anisotropy of Iceland spar was utilized by William Nicol as an efficient means for producing a plane polarized beam of light. With his famous prism, one of the beams—the ordinary ray—is shunted to one side, whilst the other—the extraordinary ray—is transmitted with but slight absorption as a pencil of wholly polarized light.

The working aperture of Nicol's prism, however, is limited by the size of optically perfect crystals of the spar, and the largest which has been made has an aperture of about 4 inches. Usually, nicols are much smaller than this, and even moderately sized optically perfect crystals of the spar have already become scarce.

Commencing with Foucault in 1857 a number of investigators—Dove, Hartnack and Prazmouski, Jamin, Glan, Feussner, Zenker, Abbe, Ahrens, Silvanus Thompson and others—have devised various prisms with the object of taking every advantage to increase the aperture and economize the precious spar.

Nothing has yet been devised which equals the nicol for transparency and for the perfection of the polarization of the transmitted light; but when large apertures are required the only alternative has been the reflecting polarizer, which produces an imperfectly polarized beam with much loss of light. The recent work of E. H. Land, who makes use of the dichroic properties of certain substances, has, however, resulted in simple means for filtering out of common light a component with high percentage plane polarization by transmission through any sized aperture desired.

To understand Land's invention fully, it must be remembered that optical anisotropy may be manifest as double refraction in which the ordinary and extraordinary rays are transmitted with unequal absorption, when the difference of the coefficients of absorption may be called true dichroism.

The decrease in the intensity of the light when passing through an optically anisotropic plate may be partly due to scatter and partly due to true absorption. The difference of the coefficients of scattering is called 'dityndallism', and this with the true dichroism makes up the total dichroism. In most crystalline substances the dityndallism is negligible, but in colloidal anisotropic systems it may be important.

The absorption depends not only upon the thickness of the plate but also upon the wave-length, and consequently in nearly all dichroic crystals the transmitted light is coloured. The outstanding and historical example of a dichroïc uniaxial crystal, in which the transmitted light is strongly polarized and nearly colourless, is tourmaline. In certain tourmalines the ordinary ray is completely absorbed, but the extraordinary ray vibrating in a plane parallel to the trigonal axis is transmitted unfortunately with so much absorption as to render most good polarizing tourmalines useless in feeble illumination.

In 1851 Dr. William Bird Herapath[1] discovered a remarkable compound of iodine and quinine sulphate, iodosulphate of quinine, $4Qu.3H_2SO_4.2HI.I_4.6H_2O$, which aroused great interest at the time and was afterwards called Herapathite by Haidinger. Later, he discovered a similar dichroic compound of strychnine.

The double refracting Herapathite can be crystallized in minute hexagonal plates, and it has been stated that such a plate 1/200 inch thick will completely absorb one of the rays, permitting the other to be transmitted with scarcely perceptible absorption. Large crystals cannot be made, though some were made large enough by Dr. Herapath to be used by Beale as polarizing components in the microscope[2]. These crystals were used for the microscope very shortly after their discovery, but their permanence could not be depended upon[3]. If exposed to the air or mounted in Canada balsam dissolved in xylol, the iodine disappears and the crystals lose their polarizing properties. They can be preserved, however, in Canada balsam dissolved in ether.

I have succeeded in making crystals 2–3 mm. in diameter, but they were not flat and far too friable to be ground into parallel plates.

Dr. Herapath's arresting discovery seems to have passed into oblivion until Land succeeded in making a thin sheet of nitrocellulose packed with ultra-microscopic crystals of Herapathite with their optic axes all parallel to one another. Such a sheet behaves like a single extended crystal, with the difference that since the crystalline particles overlap in the direction of the thickness of the film the transmitted beam is absorbed more than it would be in a single crystal and the sheets have a smoky brown appearance.

In his patent specification[4], Land describes processes by which these sheets may be made. One way is to prepare a gel-like mass containing Herapathite which is thoroughly mixed with a viscous nitrocellulose or cellulose acetate solution. Since the particles are asymmetrical, they will orient themselves in the same direction when the viscous mass is extruded through a slit-like die. But the retarded flow of the outer surfaces of the material during its passage through the die as compared with the flow of deeper layers will give rise to surface shear upsetting the regular arrangement of the crystals. To overcome this difficulty a layer of the charged plastic is placed between two layers of uncharged plastic before extrusion through the die. The middle charged layer then flows with practically uniform velocity over the cross section and the particles are uniformly distributed parallel to one another.

Another method is to place the viscous polarizing material in contact with a substratum of viscous non-polarizing material, such as fluid celluloid or other colourless oily ester, spread upon a glass plate or sheet of celluloid in such a way as to stretch the polarizing medium. Orientation of the particles may also be brought about by subjecting a diluted colloidal suspension to an electric or magnetic field during the setting of the mass.

It is by some such means described by Land that the Polaroid Corporation of Boston, U.S.A., has succeeded in manufacturing the 'Polaroid' sheets of polarizing material now on the market. Other firms have secured the right to employ the material in special applications. Thus, one firm supplies Polaroid analysers and polarizers for the microscope, as well as for projecting lanterns and other instruments. Another manufactures ophthalmic instruments employing Polaroid. The Eastman Kodak Co. employs the material for photographic purposes under the trade name of 'Pola Screen'; the Royal Photographic Society has awarded the Hood Medal to Mr. Edwin H. Land for his meritorious invention.

There are two grades of Pola screen at present available—Types I and II. Type I consists of sheet material cemented between glass plates of *A* or *B* quality intended for use over the camera lens. The *A* quality glass plates are optical flats hand surfaced of the highest quality, and the *B* plates are of optical glass of good quality which will not affect definition. The plates are mounted in light metal circular rims with an aperture up to 4½ inches. Similar screens with Bakelite rims are also supplied in Great Britain by Polarizers Ltd. Type II is intended for use over light sources and consists of a Polaroid sheet cemented to a single plate of glass. In this form the polarizer slightly diffuses the incident light, but may be had in sheets up to 12 inches square. The amount of polarization by single plates of Polaroid and the transmission of ordinary light through two films parallel and crossed as well as two plates parallel and crossed has been determined by L. R. Ingersoll, J. G. Winans and E. H. Krause[5] for wave-lengths 4000A. to 20,000A. and by J. Strong[5] for wave-lengths 3000A. to 11,000A.

As the behaviour of this new material cannot be judged without some knowledge of such measurements, the following table gives the average figures taken from the curves obtained by these authors. There appears to be some variance with different samples.

The dichroic properties of the material can be plainly seen by the smaller percentage of polarized light in the violet and red ends of the spectrum as compared with the intermediate portions where the absorption of one ray is almost complete. Consequently when a bright light is observed through two crossed plates, it is seen to be coloured a deep red.

The transparency of films and plates to ordinary light is also not without interest. The material is opaque to the ultra-violet but very transparent to the infra-red, when parallel or crossed ; so that a pair of crossed films will serve as an excellent infra-red filter and will not polarize the transmitted radiation. The transparency of films in the visible spectrum is not so great as that of plates, due apparently to greater scatter, but of course the glass in the plates absorbs a large percentage of the infra-red.

	Percentage Polarization	Percentage Transmission			
		Films		Plates	
		Parallel	Crossed	Parallel	Crossed
3000A	—	0	0	0	0
4000	70	1·5	0	22	5
4500	70	12	0·5	28	4
5000	95	13	0	32	3
5500	98	15	0	33	2·5
6000	98	16	0	33	2·5
6500	96	25	0	33	2·5
7000	91	34	2·5	32	2
8000	32	63	62	28	5
9000	9	77	77	37	29
1 μ	5	85	85	39	43
1·1 μ	—	85	85	41	41
1·5 μ	1	—	—	—	—
2·0 μ	0·5	—	—	—	—

In a subsequent patent specification[6], Land describes the use and preparation of films of nitrocellulose containing polarizing ultra-microscopic particles of inorganic periodides, particularly purpureocobaltchloridesulphateperiodide. He states that films prepared with particles of this substance, suitably oriented, give complete polarization, with a colourless transmitted beam and extremely small loss by absorption. The material should be a great improvement on the Herapathite material.

The scientific and technical applications of Polaroid are almost unlimited. The most obvious and most important application which first springs to the mind and which is specifically mentioned by Land in his first patent specification is to the vexed problem of glare from the headlights of motor vehicles. By covering the aperture of the head lamps with Polaroid with its plane of polarization in a specified position, parallel say to the vertical plane, then an observer looking through a Polaroid screen with its plane of polarization parallel to the horizontal plane will see the head lamp merely as a faint dark red source, but all objects illuminated by the headlight will be seen almost as clearly as without the screen. The light from the head lamp is polarized with its intensity reduced by a little more than fifty per cent, but this polarized light is depolarized into ordinary light when diffusely reflected from the surfaces of objects, the visibility of which is therefore unimpaired by the observer's crossed screen.

To be effective as an anti-glare device on the road, it would be necessary to enforce the use and the manner of using this material by legislation. But it is not manufactured in Great Britain, and, moreover, the patent rights are in the hands of one body which is very much alive to the immense value of this epochal invention.

Since ordinary light when specularly reflected from non-metallic surfaces at about 32° to 37° to the surface is strongly polarized in the plane of incidence, that is, the vibrations are parallel to the surface, it will be absorbed by transmission through a Polaroid film with its plane of polarization parallel to the surface. Consequently the details of reflecting objects can be seen more clearly through Polaroid films and are invaluable in photographic work. A Pola screen placed in front of the lens of a camera will enable otherwise impossible photographs to be taken obliquely through glass or water. Oblique reflections which hide surface detail or interfere with good composition can be subdued.

A single screen used in the form of spectacles will give the observer all the above advantages and aid his view of glazed pictures obstructed by surface reflections in picture galleries. But such spectacles will not cut out effectively the surface glare of roads from the setting sun which is so troublesome when motoring, since such oblique reflections are scarcely polarized.

If, however, a second screen adjustable by rotation is used in the spectacles a variable anti-glare goggle is at once available, and has been described by E. H. Land in a patent specification[7]. The screens arranged in this way can be used as a practically neutral variable density device of great simplicity and utility in many applications. The light scattered from the blue sky in and about a plane perpendicular to the sun's rays is strongly polarized in the plane containing the sun and the ray from the sky. Consequently the tone of a clear blue sky in a direction perpendicular to the sun's rays can be varied in photography from light to very dark by rotation of a Pola-screen placed in front of the lens, and surrounding objects can be made to stand out in a remarkable manner.

When the illumination is plane polarized by placing a Pola screen type II over the light source, various useful effects can be obtained by observation or photography through a second screen. Though polarized light becomes ordinary light when diffusely reflected, it retains its polarization when specularly reflected from non-metallic surfaces, and troublesome reflections can be cut out by the second screen.

Reflection from metallic surfaces, however, is more complicated. Common light is only partially polarized by metallic reflection, and plane polarized light is reflected as such only when the plane of polarization is in or perpendicular to the plane of incidence. At all other azimuths, plane polarized light is converted into elliptically polarized light by metallic reflection and so the second screen cannot completely cut out such reflections.

The advantage of polarized illumination depends upon the fact that specular reflections can be quenched by the second screen but reflections depolarized by scatter pass through it. When semi-transparent objects are examined or photographed in polarized light, the surface specular reflections can be quenched, but the light diffused from deeper layers passes the second screen and such objects assume a new appearance. Thus the true texture of the skin becomes more apparent, when the illumination is intense.

It has been stated that stereoscopic cinema projection was demonstrated by the inventor of Polaroid in New York a short time ago. For this purpose the two stereoscopic film pictures are projected on to the same screen one over the other, through Polaroid plates with their planes of polarization set at right angles to one another. The audience were supplied with Polaroid spectacles with the plate over the left eye set to cut out the right-eye picture and that over the right eye set to cut out the left-eye picture. But the nature of the projection screen surface has not been disclosed. The usual interference colour effects produced by introducing plates of uniaxial crystals or substances such as Cellophane which behave optically like uniaxial crystals, between two crossed Polaroid screens, might be used for the projection of coloured backgrounds of changing hue on the stage.

The Polaroid screen will also find many scientific uses, more particularly if the somewhat fanciful prices at present demanded are very considerably reduced when mass production starts. It cannot replace the nicol in measuring instruments in which the polarization of the light must be complete, but obviously it can be used with great advantage in photo-elastic apparatus, strain viewers, and projecting lanterns, microscopes, telescopes, ophthalmic instruments in which the nicol restricts the aperture or interferes with the definition of the optical image.

Now that E. H. Land has so successfully demonstrated the possibility of manufacturing polarizing screens, without doubt attention will be concentrated upon the production of more transparent material, transmitting a higher percentage of plane polarized light uniformly throughout the visible spectrum. It would seem that when the remarkable phenomena of photoanisotropy observed by Weigert and by Zocher and Coper in recent years are more fully understood, means will be found by which we may completely control the production of plane, circularly or even elliptically polarized light.

Weigert discovered that plane polarized light may turn an isotropic solid colloidal system into an anisotropic one with double refracting and dichroic properties. By exposing a dry layer of silver chloride suspended in gelatine to common light a bluish-red photochloride is formed. If now the photochloride is exposed to intense polarized red light the photochloride becomes double refracting and dichroic, with the plane of polarization parallel to that of the exciting light. Violet or ultra-violet light has no such effect, neither does the photoanisotropy develop at very low temperatures. Werner and Kuhn have found also that photoanisotropy is produced in an aqueous gel of the dyestuff cotton yellow when excited by plane polarized light.

But Zocher and Coper have found that circularly polarized light will convert thin photochloride layers prepared by chlorinating silver mirrors into layers exhibiting circular dichroism and circular double refraction. The circular dichroism produced is of the same sign as the dichroism produced by plane polarization. That is to say, the photoanisotropic layer is more transparent to circularly polarized light of the same sense as the exciting red light than to circularly polarized light of the opposite sense.

Circular double refraction in which the circularly polarized wave of one sense is retarded relatively to the wave of the opposite sense of rotation is simply optical activity, and this is the first case in which optical activity has been produced by light itself.

For those who are not fully acquainted with these interesting and important investigations on photoanisotropy it might be mentioned that a brief and lucid description of them has been given by Prof. H. Freundlich[8], with an extensive bibliography.

Tree-Ring Chronology in American Prehistory

AN archæological reconnaissance in 1920 of the Chaco Canyon, New Mexico, on behalf of the National Geographic Society of Washington, D.C., was followed by the decision of that Society to assume responsibility for the exploration of the two prehistoric sites of Pueblo Benito and Pueblo del Arroyo. Of these, the former is the most famous and important of the prehistoric remains of the south-western United States, the ruined structure consisting of a thousand rooms of stone and adobe. Its size alone bears out the evidence of the numerous ruined pueblos immediately adjacent that this now arid area once supported a large and densely concentrated population.

The investigations of the National Geographic Society were under the field direction of Dr. Niel M. Judd. They were carried out by successive annual expeditions in the period 1921–27. In addition to the exploration of the two villages, which were the main objective, observations were made on more than forty other sites in this important archæological area. The purpose of the expedition was not merely the study of the distinctive culture of Bonitian civilization, but also to determine as closely as possible the conditions which had led to the remarkable concentration of population and efflorescence of culture at this point, and above all, the causes of the decay of this civilization before the advent of the Spaniard to the American continent.

An investigation, which began more or less as a sideline, eventually produced a result of far-reaching importance for American archæology, of which the end is not yet in sight. This was the application of the tree-ring method of dating to the chronological problem of Pueblo Bonito and other related prehistoric remains of this region.

When the expedition of the National Geographic Society in the Chaco Canyon area came to an end in 1927, it was intended to issue a comprehensive account of the exploration as a whole ; but owing to a variety of circumstances this project has had to be abandoned. The results of the expedition and the reports of those who have co-operated in the work, therefore, will appear in a series of independent papers to be known collectively as the Pueblo Bonito Series. Of these, the first, by Dr. A. E. Douglass, on the dating of the ruins by the study of tree-rings shown in the timbers of the buildings, is now available.*

The Pueblo Bonito Expedition first made contact with Dr. Douglass in 1921, when samples of timbers obtained in the first year of the expedition were submitted to him for examination ; but it was not until the following year that intensive application of the method was made to the chronological problem at this ruin. Dr. Douglass, when engaged in an attempt to correlate climatic conditions with the periodic recurrence of sunspot activity through the study of tree-ring growth in northern Arizona, had been invited, in 1918, by Dr. Clark Wissler, of the American Museum of Natural History, to attempt a determination by this method of the comparative ages of the ruins of Aztec and Pueblo Bonito. His attention was thus directed to the possibility of dating prehistoric remains by the study of beams of timber surviving in the numerous ruins of the south-west, which presumably had been subject to like climatic conditions, and of constructing from this evidence the beginnings of a time-scale. When the operations at Pueblo Bonito came to an end in 1927, the dating of the ruin had not been determined to his complete satisfaction, and the second beam expedition of 1928—the first expedition took place in 1923—was followed by a third expedition in 1929. By this expedition what had appeared a gap in the evidence was successfully eliminated.

The tree-ring method of dating elaborated by Dr. Douglass is sufficiently well known by now to obviate detailed description. The essential feature is the identification in borings or sections of timber of certain distinctive sequence groups of the ring-growth of the tree due to the influence of an identical annual succession of variation in climatic conditions. Although some thousands of specimens have been examined, no sequence has been found to be exactly duplicated in the course of a period of more than twelve hundred years. By means of the overlap in ring growth in timber at different stages of age at given points in time, it has been possible to build up a time-scale, which proceeds from living trees to historic timbers, namely, beams from buildings of known date, and from historic to prehistoric. Dr. Douglass here figures a complete series of ring growths, which extends from 1929 right back to A.D. 698. The woods which have been found best for the purpose of the investigation are the western yellow pine (*Pinus ponderosa*) and the Douglas fir (*Pseudotsuga taxifolia*), while the next best is the pinyon (*Pinus edulis*).

* National Geographic Society. Contributed Technical Papers, Pueblo Bonito Series, No. 1 : Dating Pueblo Bonito and other Ruins of the South-West. By A. E Douglass. Pp. 74. (Washington, D C.: National Geographical Society, 1935)

This elaborated time-scale has been applied to determining the age of a large number of ruins which have furnished the material from which it has been built up; but perhaps of even greater interest for the archæologist than the dating of individual structures is the precision given to the cultural periods, of which the time relation had been determined previously by archæological methods. For example, the beautiful cream-coloured Hopi ware is seen to begin in the early part of the fourteenth century, the polychrome red pottery largely filled the thirteenth, red pottery was common in the twelfth, and black-on-white ware was characteristic of the tenth and eleventh centuries. In more general terms, of the succession of cultural periods into which archæologists have classified Pueblo civilization, Pueblo III, the golden age of south-western prehistory, took its early form in Chaco Canyon about A.D. 919, reached its local climax in the late eleventh century, and probably closed with the great drought which endured from 1276 until 1299. Pueblo IV began in the early thirteen hundreds. Dating, however, is complicated by the problem of centrifugal diffusion. Pueblo culture, it is thought, probably originated at a single centre, from which it spread outwards. It is not, therefore, everywhere contemporaneous.

So far as the dating of individual ruins is concerned, Pueblo Bonito is now shown to be the oldest of the south-western ruins. Its building began in A.D. 919, and the major construction took place in the decade 1060–70, with a lesser activity twenty years later. The important site of Aztec, notwithstanding its size, was built in a period of twelve years 1110–21. The dates determined for the beginning of construction on forty-five sites range from A.D. 919 until 1417, except for two instances, dated at 1550 and 1770 respectively.

The investigation has thrown light on a number of collateral problems. For example, there is the question of the former existence in this area of considerable pine forests, which have now disappeared, and by their extinction, no doubt, contributed their share to the aridity of the area. Some specimens which have been examined were evidently dead wood at the time they were used, and the confused and almost indistinguishable rings at the end of their growth bear witness to the aridity which caused their death. This formation has been paralleled from trees which have died recently.

The evidence of the grouping of sequences of poor growth is interpreted as pointing to a succession of droughts, which recurred with extreme severity at intervals of about three hundred years. One of these droughts, the most severe, covered the closing years of the thirteenth century (1276–99); another appears from 1573 until 1593; and still another in 1890, with a period of maximum intensity from 1896 until 1904. Periods of drought earlier than these are also perceptible, which go back so far as A.D. 904. The study of these cycles should prove of importance for the future of climatology. Archæologists will look forward with keenest anticipation to the extension of this technique to conditions which will throw light on the beginnings of Pueblo culture and its dating in relation to the culture of the Basket-makers.

Obituary

Mr. R. D. Oldham, F.R.S.

RICHARD DIXON OLDHAM, whose death took place at Llandrindod Wells on July 15, was an original and independent thinker—a little too independent sometimes for those in authority. He was most widely known for his geological work in India and his seismological investigations; but he wrote on other subjects, and his writings are always interesting and suggestive. He was the third son of Dr. Thomas Oldham, F.R.S., the first director of the Geological Survey of India, and was born on July 31, 1858. He was educated at Rugby and the Royal School of Mines, and appears to have been elected to a science scholarship at Emmanuel College, Cambridge, but never took it up. His father, who had retired two years earlier, died in 1878; and he, following his father's footsteps, accepted an appointment on the Indian Geological Survey in 1879.

In the regular fieldwork of the Survey, Oldham had a wide and varied experience, chiefly in the north, ranging from Manipur to Baluchistan; and he also visited the Andaman Islands. The results are to be found in many papers in the "Memoirs" and "Records" of the Survey. In addition to his fieldwork, he edited his father's unpublished papers on earthquakes and thermal springs in India. The most important of these dealt with the Cachar earthquake of 1869, and the editing included the whole of the discussion of the observations collected by his father, a very useful grounding for his later work in seismology. He also compiled a "Bibliography of Indian Geology" (1888), and prepared the second edition of the official "Manual of the Geology of India" (1893). This was essentially a new work, though it incorporated much of the original edition; and several of the new chapters written by Oldham are of great interest to all geologists, not only to those in India. But perhaps his most important work for the Survey was the "Report on the Great Earthquake of 12th June 1897", forming vol. 29 of the "Memoirs" (1900). Seismology was now his chief interest. He was the first to show (*Phil. Trans.*, A, **194**, 135) that the disturbance set up by a great earthquake splits into three distinct forms of wave-motion which, travelling at different rates and along different paths, give rise to the three distinct phases observed in distant seismographic records.

Oldham retired from the Survey in 1903, and for some time lived in the Isle of Wight, where he was near the seismographic station of his great friend, John Milne. His seismological studies were continued; in 1906 he showed that the records of distant earthquakes indicate that the earth has a core very different in properties from the rest, and he determined its diameter approximately. He was indeed a pioneer in the application of seismology to the investigation of the interior of the earth.

In his later years, Oldham spent much time in the south of France, where he studied the history of the Rhône delta, and finally he withdrew to Llandrindod Wells.

Oldham was awarded the Lyell Medal of the Geological Society in 1908, and was president of that Society in 1920–22. He was elected a fellow of the Royal Society in 1911. P. L.

Prof. Snouck Hurgronje

WE regret to record the death of Prof. Christian Snouck Hurgronje of Leyden, the distinguished authority on the religion and customs of Islam, which took place on June 26 at the age of eighty-one years.

Prof. Hurgronje was not only one of the foremost oriental scholars of his time, but he was also a great exponent of the value in affairs of the study of living native institutions, his intimate knowledge of the languages of the East and of the customs, religion and laws of Islam having proved of signal service to the Colonial Government during his residence in the Dutch East Indies.

Hurgronje was born in 1855; and in 1885 was admitted by the University of Leyden to the degree of doctor in Semitic languages and literature for a dissertation on the Feast of Mecca. He continued his oriental studies at Strassburg, and was then appointed instructor in Arabic and the institutions of Islam at the School of Instruction for Dutch-Indian officials at Leyden. In 1884, with the object of obtaining a first-hand knowledge of the religious exercises of Islam, he went to Jiddah, the landing place of pilgrims to Mecca. Here he remained until fully equipped to enter the holy places of Mecca. This he did with pilgrims from the Dutch East Indies in February 1885, and remained in the city until the following August, living with the pilgrims and carrying out their religious observances, until the killing of the French orientalist, Dr. Huber, while trying to penetrate into the interior from Jiddah, led to his expulsion by the Turkish authorities.

In 1889, Hurgronje began his work in the Dutch East Indies, when he was sent out by the Government at The Hague to act as adviser on Moslem institutions in Java. His appointment, originally for two years only, lasted for many years, so valuable did his services prove to the Government. One of his more notable achievements was in tendering advice to the Colonial Government and the Government at The Hague, which was framed in the light of his study of Achinese institutions, and contributed largely to the pacification of northern Sumatra, where the Government had been carrying on a desultory war with the Achinese since 1873.

Although both Cambridge and Leyden had offered chairs to Hurgronje, he declined all such offers until he could regard his work in the East as completed; but he accepted the professorship of Arabic at Leyden in 1906. Here he was not forgetful of his practical experience in the East, and for the remainder of his life he continued to be a close observer of the effect of modern trends in international relations on the development of Islam, a matter upon which he produced several important and authoritative articles. He presided over the Congress of Orientalists when it met at Leyden in 1931, having also been a member of the Congress when it met previously at Leyden in 1883.

Hurgronje was the author of a large number of contributions to the literature of oriental studies. Among his best-known works are "Mekka" (1888), a study of the Achinese (1893–94), and "Une Nouvelle Biographie de Mohammed" (1894).

Dr. F. J. F. Shaw, C.I.E.

DR. F. J. F. Shaw, whose death in India was recently announced, joined the Indian Agricultural Service in 1910 as a mycologist attached to the Agricultural Research Institute, Pusa. He remained at Pusa for the whole of his service except for a short period at Coimbatore in Madras, and was engaged in research in plant pathology and work on the control of plant diseases until 1928, when he was appointed Imperial economic botanist. Even in this latter appointment much of his work was the breeding of crop plants for resistance to disease, so that he retained his interest in plant pathology in the broad sense. Of late, much of his time was occupied in administrative duties, for he was appointed director of the Imperial Institute of Agricultural Research at Pusa in 1934, and as such had the supervision of the arrangements for transferring the Institute, wrecked by the Bihar earthquake that year, to a new site near Delhi. For the last few months he was at Simla officiating as agricultural expert with the Imperial Council of Agricultural Research; but he left to supervise some of the difficult operations of the transfer of the Institute, and was overcome by the heat at Agra.

Dr. Shaw was best known for his researches on the important fungal parasites of Indian crops belonging to the genus *Rhizoctonia*, and for his studies on the diseases of jute and the control of diseases of fruit trees and pulses. He was little interested in systematic mycology, and was led astray in the identification of the difficult members of the genus *Rhizoctonia* with which he worked, but he effected a considerable advance in knowledge of their biology and morphology. Of recent years, his chief work was a study of the types of the important Indian pulse crop, pigeon pea (*Cajanus indicus*), with the object of breeding for resistance to the wilt disease caused by *Fusarium vasinfectum*; in this difficult problem, for the crop is extensively out-pollinated, he achieved a considerable measure of success. If the work can be carried to a conclusion it will be of great benefit to Indian agriculture, for the disease is extremely destructive and the parasite so completely infests the soil as to necessitate prolonged rotation if the crop is to yield an adequate harvest. Other work on similar lines has been in progress at Pusa under Dr. Shaw's control on a number of crops such as cereals, linseed, gram (*Cicer arietinum*) and other pulses, tobacco and various fibre and oil seed crops; continuity in such work is essential, and Dr. Shaw's untimely death will greatly accentuate the difficulties of carrying it on, already made serious by the aftermath of the earthquake.

Dr. Shaw, who was fifty years of age, was educated at St. Olave's Grammar School and the Royal College of Science, obtaining the A.R.C.S. and D.Sc. (London). He was made a C.I.E. in the King's birthday honours list of this year.

Prof. Kikunaé Ikeda

By the death of Prof. Kikunaé Ikeda on May 3, Japanese science loses one of its foremost students of chemistry. Some details concerning his life and work appear in the May issue of the *Proceedings of the Imperial Academy, Tokyo*. Prof. Ikeda, who was born on October 8, 1864, studied science at the University of Tokyo and graduated in 1889. During the next seven years, he taught chemistry in the Tokyo Higher Normal School, where, both by his teaching and by the text-books that he published, he greatly assisted the general appreciation in Japan of the new science of physical chemistry.

In 1896, Ikeda was appointed assistant professor of chemistry in the University of Tokyo, in which capacity he came to Europe three years later for further study of physical chemistry. During his stay in Europe, he worked in Ostwald's laboratory, where, in collaboration with Bredig, he published important work on the poisoning of colloidal platinum catalysts. He also worked for a short time at the Davy Faraday Laboratory in London. On his return to Japan in 1901, he was appointed to a full professorship in chemistry, which he held for twenty-two years. During this time he was particularly occupied with the study of chemical kinetics and the theory of solutions. During this period he was appointed chief of the Chemistry Division of the Institute of Physical and Chemical Research, and he served also on the National Research Council of Japan.

On retiring from his professorship in 1923, Prof. Ikeda continued to take an active interest in chemistry. After a stay of seven years in Germany, he returned to Japan in 1931 and established a private laboratory where he studied various problems concerned with the applications of chemistry. The high esteem in which he was held was shown on his sixtieth birthday, when his friends and former pupils arranged a celebration and raised a large sum of money which, by his wish, was given to the Chemical Society of Japan for the extension of the scientific publications of the Society.

Mr. F. S. Stacey

We regret to announce the death, on August 11, of Mr. Francis Samuel Stacey, one of the pioneers of radiotelegraphy, at the age of fifty-six years.

Mr. Stacey was a student of Finsbury Technical College, and joined Marconi's Wireless Telegraph Co., Ltd. (then known as The Wireless Telegraph and Signal Co., Ltd.), in July, 1899, at the age of twenty years. After a short period in the Company's works he was employed for some time in experimental work as an assistant to Marchese Marconi, and, in 1900, was engaged in the execution of a contract for the installation of wireless on the whole fleet of Belgian cross-channel steamers. Shortly afterwards he was transferred to Marconi's Wireless Telegraph Company of Canada, where he remained until 1910, engaged in the construction of stations, experimental work, and the operation of the Glace Bay trans-Atlantic wireless station.

Between 1910 and 1912 Mr. Stacey was employed at the Marconi station at Poldhu in Cornwall in connexion with experimental work and development of long-range high-power stations which had their birth at Poldhu. From 1912 until 1914 he was acting chief of the Constructional Section of the Marconi Company, and in 1914 became chief of one of the contract sections which deals with the supply of every kind of commercial wireless telegraph apparatus. Among other things, his department of the Marconi Co. has been concerned with the execution of contracts for nearly all the broadcasting stations in England, and a very large number in Europe, Japan, South Africa, and South America.

Mr. Stacey was married in 1909 to Miss M. McLeod, a Canadian lady, and leaves a widow and two daughters.

We regret to announce the following deaths:

Prof. Luigi Devoto, professor of industrial diseases and director of the clinic of industrial diseases in the University of Milan, on July 22, aged seventy-two years.

Prof. Aubrey C. Grubb, professor of physical chemistry in the University of Saskatchewan, known for his work on the electrical activation of hydrogen and nitrogen gases, on July 29, aged fifty-two years.

Dr. H. A. D. Jowett, manager of the Wellcome Chemical Works, Dartford, an authority on medicinal alkaloids, on August 10, aged sixty-six years.

Jean-Baptiste-Louis Romé de l'Isle (1736–90)

AUGUST 26 is the bicentenary of the birth of Jean-Baptiste-Louis Romé de l'Isle, an assiduous student of natural history and a writer on crystallography. He was born at Gray in Haute-Saône. After being educated in Paris, he sailed to the East Indies as secretary of a company of artillery, and in 1761 became a prisoner of the English at Pondicherry, being held captive for three years. Having acquired a taste for science, on his return home he became a student of the chemist Balthasar-George Sage (1740–1824) and applied himself to mineralogy, forming a mineralogical cabinet, and in 1772 publishing his "Essai de Cristallographie". This work he afterwards enlarged and published in 1783 under the title "Cristallographie, ou Description des formes propres à tous les corps du règne mineral dans l'ètat de combinaison saline pierreuse ou métallique". It contained tables of all the crystals then known. Another subject to which he devoted much time was metrology, stimulated no doubt by the chaotic state of the weights and measures in France at the time. He collected a great mass of material relating to the subject, some of which he embodied in his "Métrologie, ou Table pour servir à l'intelligence des poids et mésures des anciens . . ." which appeared in 1789, the year the Revolution broke out. Through his close application to study he suffered somewhat from failing eyesight, and this being brought to the notice of Louis XVI, he was granted a small pension, although he had held no official position. His death took place in Paris on March 7, 1790.

Water Resources and Supply Control

THE Parliamentary Joint Committee appointed to consider and report on measures for the better conservation and organization of water resources and supplies in England and Wales has, in its report just issued (London : H.M. Stationery Office. 3*d*. net), made some caustic comments on the attitude of the Ministry of Health towards the general aspect of the whole question of national water administration, pointing out the one-sided nature of the composition of the Advisory Committee on Water, upon the reports of which the proposals of the Ministry of Health have been framed. The Joint Committee states that it is of opinion "that the methods of the Ministry of Health justify in no small degree the criticisms that have been levelled against them by reason of their apparent failure either to consider the point of view of, or to consult with, opposing interests before submitting their proposals to the Committee". Accordingly, the Committee does not see its way to endorse the memorandum submitted by the Ministry of Health, in which it is proposed that power should be given to the Minister to make orders scheduling areas within which the conservation of surface or underground water resources for water supplies is of public interest, the object of the orders being to prevent water from being drawn from those areas for water undertakings, or for industrial or other purposes, without his consent. The evidence of witnesses who appeared before the Committee showed unmistakably the hostility of interests connected with industry, agriculture and fisheries to any such form of dictatorship in water administration, alleging the incompetence of the Ministry of Health to appreciate needs other than those which are associated with water for domestic and sanitary uses. The Committee's judgment is that all proposals for the appropriation of supply areas should remain, as heretofore, under direct parliamentary control, and it is unable to recommend any procedure other than the continuance of that by Private Bill.

Proposed Central Advisory Water Board

THE principal constructive feature of the Joint Committee's report is its recommendation that a statutory Central Advisory Water Board should be set up, comprising representatives of the various ministries affected and other interested bodies, such as catchment and fishery boards, water undertakers and mill and riparian owners. In addition, it recommends the extension and development of the nine Regional Advisory Committees, at present in existence in various parts of the country, by the addition of three or four others, so as to cover the remaining areas, and it expresses the view that these bodies, which are purely voluntary with representation confined to water undertakers and the Ministry of Health, should be enlarged to include representatives of the catchment boards and other interests, and that they should discuss and report to the Central Advisory Water Board on any difficulties or differences and on general matters concerning their respective areas. The Central Board would collect and marshal all the available statistical data and information of the country's water resources and requirements, and advise the appropriate Minister as to the initiation of any schemes or proposals considered necessary in the public interest. The Central Board should further submit reports to all Select Committees of Parliament considering Bills on water supply, and make an annual report to be laid before both Houses of Parliament. The Joint Committee's report also deals with the question of compensation water, admittedly beset with complications, some of which are pointed out. Rejecting the formula proposed by the Ministry of Health, and indeed any formula, since no suitable formula can be found for general application, the Joint Committee concludes its report with a statement of the considerations which must apply in the assessment of compensation water, each case being, of necessity, determined on its particular merits.

Native Medical Practitioners in the South Seas

The Government of Fiji recognized many years ago the need for a medical service for the native population, but realized that the employment of European doctors on a large scale was impracticable on account of cost, and that practitioners of their own race would be best suited to attend to the needs of the natives. The Government therefore established the Native School of Medicine at Suva for the benefit of Fijians, and for many years its 'graduates' did excellent work. A few years ago, the Rockefeller Foundation commenced investigations upon the problems of disease and of depopulation in these islands, and was so impressed with the success of this Native School that it offered to co-operate with the Fijian Government, and suggested the training of natives from eight groups of islands in the School at Suva. The Government agreed to work in conjunction with the Foundation, and the School was then reorganized and reconstituted in its present form. The School is residential, and is attached to the Suva Memorial Hospital. Its direction is in European hands, the students are under reasonable discipline, and the cost of maintenance is small—something less than £3,000 a year—which is contributed in various ways.

Sir James Barrett, Vice-Chancellor of the University of Melbourne, gives an account of the activities of the School in an article in the *Morning Post* of August 7. The students are mostly Polynesians, and must pass a matriculation examination before admission, based upon the New Zealand proficiency examination, which ensures a good knowledge of English. The first year of the present four-years' course is devoted to elementary basic science, and the remaining three years provide the student with a sound, practical medical training in the Suva Hospital. After graduation, the practitioners return to their own islands as health or medical officers among their own people. The initial salary of a graduate is £60 a year, rising to a maximum of £150, which suffices for local requirements. If no European doctor is available, as is often the case, the native practitioner may attend to the medical requirements of Europeans. At present, eighty-four practitioners are at work, distributed over Fiji, Samoa, Tonga, the Cook Islands, Gilbert and Ellice Islands, Solomon Islands, and New Hebrides; of these, Fiji takes fifty-six. In addition, native nurses have been trained in large numbers; the Suva Hospital is staffed by twenty European and twenty Fijian nurses, and there are forty-seven obstetric nurses in Fiji alone. Sir James Barrett endorses the very favourable opinion on the efficiency of the School and of the practitioners it has trained expressed by Profs. Wright and Buckmaster, who, having visited Australia and New Zealand on behalf of the Royal College of Surgeons of England, passed through Suva on their return journey. Sir James envisages the adoption of some such system to meet the medical needs of the natives in other parts of the British Empire, referring to the existence of somewhat similar schools already founded in West Africa and Uganda.

The Radcliffe Observatory in South Africa

The 'turn-over' article in *The Times* of August 7 by Mr. H. E. Wood, the Union Astronomer, deals with astronomy in South Africa in general, and refers in particular to the forthcoming re-establishment of the Radcliffe Observatory at Pretoria. The history of astronomy in South Africa begins in 1685, when Father Tachard called at the Cape on his way to Siam and determined the longitude by observations of Jupiter's satellites. During the next century, two expeditions visited the Cape, and 1820 saw the foundation of the Royal Observatory, which has made such notable contributions to our knowledge of the southern stars. In 1834 Sir John Herschel landed there and made his famous catalogues of nebulæ and double stars. There are now four other observatories in South Africa: the Union Observatory and the southern station of Yale University Observatory at Johannesburg, and those of Harvard and Michigan at Bloemfontein. The Radcliffe Observatory, for more than a hundred and sixty years at Oxford, will, it is hoped, have started its new life at Pretoria within the next two years. Good progress is being made with the construction of its 74-inch reflector by Sir Howard Grubb, Parsons and Co. This will differ in several respects from its sister telescope at Toronto, as it will have, in addition to facilities for observation at the Newtonian and Cassegrain focuses, an arrangement for sending the beam of light down the polar axis to a fixed spectrograph, and it will be driven by a synchronous motor, the frequency of the alternating current being controlled by a tuning fork. The disk of Pyrex glass for the large mirror has been cast by the Corning Glass Co. and is now being annealed. The five secondary mirrors will be of fused silica, and the disks for these are being made by the Thermal Syndicate, Ltd.

Archæological Excavations in Britain

With the coming of university and school vacations, numbers of voluntary workers are released for archæological investigations in the field. Since July, excavations have been resumed or initiated on many sites in Britain. The scheme of training in field work through voluntary assistance organized by Dr. R. E. Mortimer and the late Mrs. Wheeler is again in being, this year on an extended scale. Nearly a hundred students drawn from universities in the British Isles, Australia, India, Canada, the United States and China are at work on the continued excavation of Maiden Castle, near Dorchester, under the direction of Dr. Wheeler and Col. C. D. Drew. Although the season has only just opened, some important results already have emerged. On the hill-top in the neighbourhood of the temple of the Roman period discovered in 1934, according to a report in *The Times* of August 14, further stone age habitations, with stone implements and pottery, have been discovered. A series of pits has been uncovered, in which were pottery and animal bones, including those of large oxen of a type now extinct. The neolithic site underlying the fortifications is also being explored. Extensive areas containing stone implements and pottery have been opened up; and a stone age trench now being examined is found to be covered with a well-marked line of turf underlying the later prehistoric rampart. It contains large masses of material of the stone and early bronze ages, while on top of the trench numerous sherds of elaborately decorated Early Bronze Age pottery are being identified.

EXCAVATIONS have also been resumed on behalf of the Ipswich Museum under the direction of the curator, Mr. Guy Maynard, on the Stanton Chair Farm Roman site between Ixworth and Stanton in Suffolk, where investigations were initiated last autumn as a result of the observation of Roman potsherds and tile fragments in a field. Although it is known that the area of the site is at least two hundred feet across, operations at present are confined to a narrow strip, as the ground is under crops. Work, accordingly, has been concentrated on clearing the remains of a bath-house, of which the hypocaust pillars are well preserved, and a drain from the cement floor of an adjacent room still remains. Two levels of flooring and coins of Marcus Aurelius (A.D. 161–186) and Eugenius (A.D. 393) suggest a prolonged, but interrupted occupation. Six weeks of excavation at Castle Dore, an Iron Age hill-fort, near Fowey, in Cornwall, under the direction of Mr. Ralegh Radford, with the unemployed for labour, has confirmed previous conclusions as to its character. It was evidently a strong point commanding the ancient prehistoric road and trade route across the peninsula. It is now considered beyond reasonable doubt that this was, as has been suggested, the palace of the King Mark of Arthurian legend. Students of the University of Liverpool excavating, also with the assistance of local unemployed, on Eddisbury Hill, Cheshire, have brought to light traces of an ancient fortress in the form of walls of local sandstone, five to six feet in height, in an excellent state of preservation.

Ultra-short Wave Radio Communication

THE practical application of ultra-short waves to radio communication made a step forward on June 11, when R.C.A. Communications Inc. gave a public demonstration of their new circuit connecting New York with Philadelphia. A brief illustrated description of this demonstration is given in the June issue of *Communication and Broadcast Engineering* (U.S.A.). The circuit operates over a distance of about 91 miles with the aid of two automatic relay stations situated between the terminal stations at New York and Philadelphia, the longest individual link being 36 miles. A two-way service is provided, and the six wave-lengths required are in the neighbourhood of three metres; the stations are equipped for the transmission of drawings, typescript and other visual material in facsimile, with simultaneous operation of typewriter and telegraph channels. The article referred to above includes a schematic diagram of the circuit which is reproduced from one actually transmitted to New York by the facsimile circuit. The transmitters make use of resonant line circuits in order to secure frequency stability, while the receivers incorporate the new acorn tubes specially produced for ultra-short wave purposes.

AN interesting feature of the new installation is the method by which the unattended relay stations may be turned on or off from either of the terminal stations. The receivers at each of the four stations are always alive and available for reception from their corresponding transmitters. When it is desired to make the circuit ready for traffic, New York or Philadelphia sends out a tone modulation on its carrier wave. This tone is accepted by the receiver at the first relay station, and is caused to start up its own transmitter, which then passes the tone modulation on to the second relay station. The operation is repeated here and also at the other terminal station, where the tone is re-transmitted back through the relay stations on the return circuit. Thus when the tone signal is received back at the terminal station from which it originated, it is known that all six transmitters are in operation and the radio circuit is ready to pass traffic. When the circuit is no longer required, the tone is removed and the transmitters are automatically switched off, one by one, in the same sequence.

League of Nations Reform

IN a pamphlet entitled "Anarchy or Peace", Lord Davies discusses the dangers of the present situation in Europe and the possibilities of avoiding the outbreak of an even more disastrous European war (London: The New Commonwealth. 9*d*.). Referring to the defects of the League of Nations as demonstrated by recent events, Lord Davies asserts that these were due to the absence of an equity tribunal and international police force, and more particularly to the lack of cohesion and determination on the part of States members of the League. Accordingly, he heavily discounts a good many of the proposals to reform the League as designed rather to deprive the League of the very functions which would enable it to secure the peace of the world if its machinery were honestly and whole-heartedly used. Proposals to substitute a series of regional pacts are only too certain to plunge us back in the pre-War system with its inevitable outcome. Lord Davies argues that the only solution of our present dangerous situation lies first in the creation of peaceful procedure for the settlement of all disputes and the revision of treaties. For this purpose, in default of a more satisfactory solution, an equity tribunal holds the field. Secondly, an international police force is required, and he urges once more the equipment of a European air police force under the control and direction of a neutral authority, a reconstituted League. This force must be superior in numbers and equipment to the national air force of any European State which refuses to join in the guarantee. Only a scheme on these lines will suffice to restore the confidence of the smaller powers in the integrity and good faith of the great powers, and endow the League with the superiority of force essential for the establishment of the rule of law.

Liverpool Learned Societies

The newly issued handbook of the Associated Learned Societies of Liverpool and District shows there are about four thousand members of the twenty-four scientific, industrial, literary, art and educational societies in the association. One of the largest of the industrial societies, the Liverpool Engineering Society, has some seven hundred members, and the Liverpool Naturalists' Field Club is the largest of the Nature and outdoor societies. Since the last handbook was issued ten years ago, the number of learned societies in the association has fallen by two. Local societies which have increased their membership in the past ten years are the British Association of Chemists, the Institute of Chemistry and the Liverpool Naturalists' Field Club; those that have remained at the same strength include the local branch of the Pharmaceutical Society and the Amateur Photographic Association, while those that have declined in membership somewhat include the Liverpool Botanical Society, Geological Society, Biological Society, Literary and Philosophical Society, Astronomical Society, Engineering Society, Lancashire and Cheshire Entomological Society, Society of Chemical Industry and the New Education Fellowship. The Associated Learned Societies of Liverpool and District was formed in 1922, though since 1880 there had been a scheme of co-operation between local societies, chiefly for staging annual exhibitions and soirées of their activities. The work of the present association includes holiday prize contests in the local schools, outdoor and indoor joint meetings of an educational nature, periodical public scientific exhibitions, lectures, etc., and various schemes for closer co-operation amongst the various learned societies of the district.

Research and the Jute Industry

The prosperity of Bengal, both agricultural and industrial, is dependent very largely on jute, and the intense period of depression which has overtaken the industry since 1929 has caused widespread distress. The Agricultural Commission, of which the present Viceroy was chairman, in a strongly worded paragraph of its report, directed attention to the necessity for the application of scientific methods in the industry; the position has since been surveyed by Dr. S. G. Barker. In the March issue of *Science and Culture*, Dr. Barker's report is discussed. Dr. Barker has recommended a comprehensive scheme of research which includes the establishment of a laboratory with arrangements for the collection of general and technical information and for foreign representation. This new organization is estimated to cost £27,000 per annum, and it would be under the control of the Jute Mills Association. *Science and Culture* appears to doubt whether the control suggested by Dr. Barker is likely to prove successful, since it is feared that the mill owners may be prone to look for immediate financial returns. It is suggested that a scheme organized on the lines of the Indian Central Cotton Committee might be more advantageous. In view of the urgency of the problem, we regard the nature of the controlling body to be of minor importance, since the success of the scheme will depend mainly upon the director of research and upon the personnel of the new laboratory. It is gratifying, therefore, to learn that the Government of India has already accepted Dr. Barker's proposals, and that it has appointed an Indian Central Jute Committee. The Committee will be financed by Government, which will place at its disposal approximately £30,000 per annum for a minimum period of five years. We extend a cordial welcome to this new research organization, which we have no doubt will do much to restore the ancient prosperity of Bengal.

Road Transport Vehicles

Instructive figures are given in *World Power* of June showing the relative progress made by the three principal types of road transport vehicles—tramways, motor-buses and trolley-buses. In 1930–31, tramways transported 72·7 per cent of all passengers, the motor-bus 24·2 per cent and the trolley-bus 3·1 per cent. In 1934–35 the figures were 59 per cent, 35 per cent and 6 per cent respectively. Although the tramways with 2,479 million passengers in 1934–35 still convey more persons than the motor-bus and trolley-bus combined, the decline of tramway passengers since 1930–31, when it was 3,018 millions, has been continuous. During the year 1935, the number of passengers carried by the trolley-buses was 255 millions, an increase of 36 per cent on the preceding year. The London Passenger Transport Board recently reported an increase of 20 per cent in the London area along trolley-bus routes. It has been calculated that an oil-driven bus would require a 250 horse-power engine to equal the performance of a 100 horse-power trolley-bus with a capacity of 36 seats carrying a full load up a 7 per cent gradient at a speed of 30 miles per hour. From the point of view of national economy, it is a pity, although trolley-bus progress is satisfactory, that it is not making more rapid headway. In the near future, it may be of primary importance to consume home-produced fuel to produce the necessary motive power for traction. When the traffic is very heavy, electric tramways are the most economical, but tram-cars often stop the traffic to unload passengers, whilst trolley-buses can unload them directly on the pavement.

A Horticultural Colour Chart

The naming of colour is notoriously difficult, and it is unfortunate that the standard works by Ridgway, Oberthur and Dauthenay, and others, are either out of print or too expensive to have wide application. Gardeners are, perhaps, the community most in need of a comprehensive manual portraying accurate shades of colour, and the Royal Horticultural Society is to be congratulated upon its attempt to meet this pressing need. It is proposed to print a volume of a hundred colours, each in four shades, and, if successful, to follow it by a second volume of similar dimensions. The plates would be either loose in a cover, or held by a loose-leaf binder, and the estimated price is 10*s*.

per volume. This, however, may possibly be reduced if sufficient applications follow the prospectus now issued. A specimen sheet indicates that each colour would be named, and referred also to the British Colour Council's classification, to the "Repertoire des Couleurs", and to the standards of Ridgway and Ostwald. A brief history of the name appears, horticultural examples are cited, and French, German, Italian and Spanish synonyms are given. The chart should have great utility, not only in the garden, but also wherever colours have to be compared with accuracy. A preliminary application form is now available, and those interested should communicate with the Royal Horticultural Society, Vincent Square, S.W.1. It is expected that the first volume will appear towards the end of 1936 or early in 1937.

Medal Awards for Inventions

THE Council of the Institute of Patentees has decided to suspend the award of the Institute Bronze Medal and in place thereof to substitute the Institute's Silver Medal to rank equally with the Founder's Silver Medal. These medals will be awarded in each section of the Exhibition of Inventions to be opened in the Central Hall, Westminster, S.W.1 on September 30 and in Newcastle on November 25; therefore ten silver medals will be awarded throughout the five sub-sections of the New Inventions Section of the Exhibition. The Gold, Silver and Bronze Certificates will be awarded as in previous years. As the Institute proposes to organize a series of exhibitions throughout the country, it has been decided that the Grey-Wilson Memorial Gold Medal, supported by cash prize, together with the Yorkshire Medal, will be competed for during January of each year, the successful exhibitors at any Exhibition organized by the Institute being eligible to compete. The Yorkshire Medal is a new medal which was provided for under the will of the late Mr. Hoffman-Wood, an architect of Addingham, Yorkshire, who died three years ago, and the Institute will make recommendations annually to the trustees regarding its award. The medal is valued at twenty-five guineas, and sufficient funds are available for an award in perpetuity. The award of the Yorkshire Medal must be for an invention not relating to warfare.

International Naval Architecture and Marine Engineering

THE first international meeting of naval architects and marine engineers to be held in the United States takes place in New York on September 14–19, at which papers will be read dealing chiefly with safety of life at sea and large Atlantic liners. The Dominion of Canada, France, Germany, Great Britain, Italy, Japan, Spain and Sweden are sending delegations at the invitation of the Society of Naval Architects and Marine Engineers of New York. The British delegation, under the leadership of Lord Stonehaven, president of the Institution of Naval Architects, and Dr. J. T. Batey, president of the North-East Coast Institution of Engineers and Shipbuilders, will number about a hundred, including ladies, and will represent the Institution of Naval Architects, the Institute of Marine Engineers, the Institution of Engineers and Shipbuilders in Scotland, and the North-East Coast Institution of Engineers and Shipbuilders.

International Congress of the History of Science

THE fourth International Congress of the History of Science will meet in Prague, in 1937, during the last week of September. The principal theme of the Congress will be "Science in the Eighteenth Century". The chairman of the Congress and of the Organizing Committee is Prof. Quido Vetter, the actual president of the International Academy of the History of Science. The announcement was made and discussed at the meeting of the Academy of the History of Science at Cluj (Rumania) in conjunction with the International Committee of Historians, in April last. During the meeting, several papers of great interest were read: (1) A. Mieli, "Our Present Knowledge of Arabian Science"; (2) Prof. A. Reymond (Lausanne), "Occult Sciences and Exact Science in Ancient Times"; (3) Prof. A. Singh (Lucknow), "History of Trigonometry in India"; and (4) Prof. V. Bologa (Cluj), "Foreign Influences on Rumanian Medicine". In a business session of the meeting, Drs. Reymond, Ulrich, Sergescu, Singh and Greenwood read reports on the organization of the teaching of the history of science in their various countries. The "Chronological Repertory of the Exact Sciences during the Sixteenth Century" was adopted for publication as a special number of the *Bulletin du Comité des Sciences Historiques*.

British School of Archæology at Athens

IN October next the British School of Archæology at Athens will celebrate the fiftieth anniversary of its foundation. As part of the celebration an exhibition will be held at the Royal Academy of Arts, Burlington House, London, to illustrate the discoveries in Greece and Crete, which have resulted from the work of the School. A special section of the exhibition will be devoted to the Minoan civilizations of Greece and the excavations at Knossos, which were conducted by Sir Arthur Evans, honorary student of the School, and in which the architects of the School took part. This section of the exhibition is being prepared by Sir Arthur Evans himself, with the facilities given him by the authorities of the Ashmolean Museum, Oxford, to which the antiquities brought from Knossos by Sir Arthur were entrusted. It is understood that the exhibition will be inaugurated by H.R.H. the Duke of Kent on October 13, at 3 p.m., and will be open to the public from October 14 until November 14. The occasion of the jubilee of the School will also be marked by a special fund which it is proposed to raise to enable the School to increase its staff, improve its library and accommodation, and provide for the needs of the graduates who are sent to Greece in increasing numbers for advanced study by the universities.

Congrès Préhistorique de France

IT is announced that the twelfth session of the Congrès Préhistorique de France will be held at

Toulouse on September 13–16 and continued at Foix on September 17–20. This is the third occasion only on which the Congress has met since the Great War, the meetings, held biennially between 1905 and 1913, having been intermitted during and after the War until 1931. The coming session, which is the first to be held in the Pyrenean region, will afford members an opportunity to visit a number of famous and important archæological sites, such as Aurignac, Mas d'Azil, Marsoulas, Gargas, Niaux and Portel. Excursions to these are being arranged as part of the daily programme. As is usual in congresses of this character, a number of topics is suggested for the communications to be submitted. These include the earlier palæolithic of the area, the terraces of the Garonne and their quartzites, prehistoric art, the mesolithic and the neolithic periods, and artificial caves and subterranean refuges. Arrangements are being made by the local committees at Toulouse and Foix for a special exhibition of prehistoric finds from the excavations and collections of the archæologists of the two departments of Haute Garonne and Ariège. It is also to be noted that the Musée d'Histoire Naturelle de Toulouse has a collection of cave exhibits which is considered to be the finest in the whole of France. The Congress, of which M. le Comte H. Begouen will act as president, has the official support of the University of Toulouse, the municipal authorities of Toulouse and Foix, and the Departmental Councils of Haute Garonne and Ariège. Subscriptions (members, 30 francs; members receiving the report, 100 francs; associates, 20 francs) should be forwarded to the General Secretary and Treasurer, M. Ch. Schleicher, 9 rue de Verneuil, Paris (vii^e).

Announcements

AMONG the appointments and promotions in the Colonial Service recently announced are the following: C. C. Webster to be agricultural officer, Nigeria; D. A. B. Davies to be field geologist, British Guiana; H. A. Smith to be divisional engineer, Posts and Telegraphs Department, Nigeria; A. A. Strachan to be senior engineer, Posts and Telegraphs Department, Malaya.

ON August 14, M. Georges Détré, a French airman, established a new world altitude record of 14,836 metres (48,674 ft.) at Villacoublay. According to the Paris correspondent of *The Times*, this figure exceeds by more than 400 metres (1,749 ft.) the previous record set up by the Italian, Signor Donati, in April 1934. The machine used by M. Détré was a Potez 50 Special fitted with a Gnôme-et-Rhône *K*.14 engine.

The Council of the Iron and Steel Institute makes annually a limited number of grants from the research fund founded by the late Mr. Andrew Carnegie in aid of metallurgical research work. The object of the scheme is to enable qualified students to conduct researches on problems of practical and scientific importance relating to the metallurgy of iron and steel and allied subjects. Candidates, who must be less than thirty-five years of age, must apply before September 30, on a special form to be obtained from the Secretary of the Institute. The maximum amount granted in any one year will, as a rule, not exceed £100.

OF 2,590 offenders examined in the psychiatric clinic of the Court of General Sessions, New York, within the past year, less than 1 per cent were found to be definitely insane.

DR. MAXIMILIAN EHRENSTEIN, research fellow in physiology, Department of Medicine, University of Virginia, has been awarded one of the prizes of the Van't Hoff Fund by the Royal Academy of Sciences of Amsterdam in recognition of his work on the alkaloids of tobacco and the catalytic dehydrogenation of cyclic bases.

WE have received from the City Librarian of Leeds eight bulletins or catalogues of technical engineering books. They are divided into the following eight groups: (1) mechanics and materials; (2) mechanical engineering; (3) workshop practice; (4) civil engineering; (5) mining engineering; (6) metallurgy and metal working; (7) electrical engineering—part I; (8) electrical engineering—part II. Each of the catalogues is subdivided, so it is a very simple matter to find out the standard technological works dealing with a particular subject. The address is Leeds Public Libraries, Municipal Buildings.

IN the letter "Anomalies in the Fine Structure of the First Spark Spectrum of Iodine" (NATURE, June 20, p. 1030), the line λ 4060·2 is said to consist of three components: 0·000 (4), + 0·081 (3), + 0·121 (2) cm.$^{-1}$. Dr. K. Murakawa informs us a mistake occurred in his manuscript; this line should read: 0·000 (2), + 0·081 (3), + 0·121 (4) cm.$^{-1}$.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

Temporary assistant civil engineers in the Air Ministry—The Secretary (W.B.9), Room 712, Adastral House, Kingsway, W.C.2 (August 22).

A part-time teacher of zoology and/or biology in the Northern Polytechnic, Holloway, N.7—The Clerk (September 4).

An experimental assistant in a War Department establishment at Woolwich—The Superintendent, Signals Experimental Establishment, Woolwich Common, S.E.18 (September 4).

Junior scientific officers in the National Physical Laboratory, Teddington—The Director (September 15).

An instructor in electrical engineering in the Bulawayo Technical School—The Official Secretary, Office of the High Commissioner for Southern Rhodesia, Rhodesia House, 429 Strand, W.C.2 (September 19).

A professor of anatomy in the University of Manitoba—The Dean, Faculty of Medicine.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 332.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Variation of Cosmic Ray Intensity with Sidereal Time

HOURLY records of the intensity of the cosmic radiation have been made at Cape Town since February 1933 in accordance with a scheme organized by Steinke, Hess and others for the study of the radiation. The instrument consists of an ionization chamber and electrometer provided with photographic registration. The rise of collector potential is compensated every half-minute by a condenser potentiometer device, and the accuracy of a single hourly observation is 0·1 per cent.

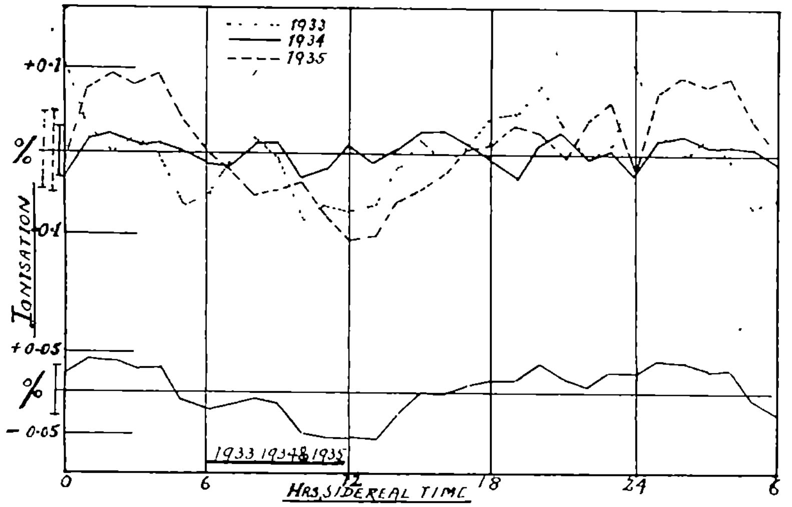

FIG. 1.

We wish to report upon the sidereal time variation during three years of observation, in which for two thirds of each month the chamber was totally enclosed in a shield of lead 10 cm. thick. Each observation has been reduced to a standard pressure of the absorbing atmosphere. Hourly means of intensity have been plotted in the upper set of curves (Fig. 1) for the years 1933, 1934 and 1935, and the combined observations for the three years are shown in the lower curve. The total number of hours of observation is 14,094. Probable errors (root mean square deviations) are indicated by vertical lines on the left-hand side.

It will be seen that the lower curve shows a variation of some 0·04 per cent of the mean, roughly sinusoidal, with maximum at about 24 hr. local sidereal time and minimum at 12 hr. A similar variation is found in the separate curves for 1933 and 1935, but is not definitely indicated in 1934. A variation of this character and phase has been noticed in the observations of Hess and Steinmaurer[1] on the Hafelekar in 1932. Compton and Getting[2] have ascribed it to the effect of the galactic rotation, which if the rays came uniformly from outer space would cause a maximum to be observed in both hemispheres at 21 hr. local sidereal time. They have pointed out the importance of observations in the southern hemisphere, for if the effect observed in the northern hemisphere were due to a seasonal change in the well-known solar diurnal variation, that in the southern hemisphere should show a maximum at 9 hr., being shifted in phase by 12 hr.

Since no such phase shift is observed, we conclude that the very small variation found in both hemispheres is a true sidereal time effect.

Measurements of Cosmic Ray Intensity in a Deep Mine

IN a coal mine in the neighbourhood of Budapest, at a depth of 315 m. below the surface, we made measurements of the cosmic ray intensity with triple coincidence apparatus. To obtain still thicker layers of material we measured the intensity at different angles from the vertical, using a very narrow aperture. The results of these experiments show that cosmic rays penetrate through a layer with a thickness of 2,500 m. water-equivalent. For corpuscular rays this will mean that the energy of the particles must surpass 10^{11} e.volt, using the formula of Bethe. The intensity distribution was found to be as follows: 1,700 coincidences per hour on the surface, 0·78 coincidences per hour at an effective depth of 700 m. of water and 0·09 coincidences per hour at 2,500 m. effective depth.

We found, further, that cosmic rays may produce showers even after passing through 700 m. water-equivalent, and that the penetrating power of the shower-particles is of the same magnitude as that usually stated for level measurements.

Ranges of Particles emitted by Samarium

In view of some divergences in the determinations of the range of the α-particles of samarium, Prof. Wertenstein suggested that I should make some new experiments on this subject.

The ionization chamber used for determinations of ranges consisted of a spherical glass bulb, of 6·9 cm. radius, with silvered inner walls, and a concentric steel sphere of 1 cm. radius, on which a thin layer of the substance under examination could be deposited. This sphere was connected to a Hoffmann electrometer, while the bulb was put into communication with a vacuum pump. The ionization due to samarium was measured at different pressures. The sensitivity of the electrometer varied within small limits, but was on the average 30,000 ions for a division.

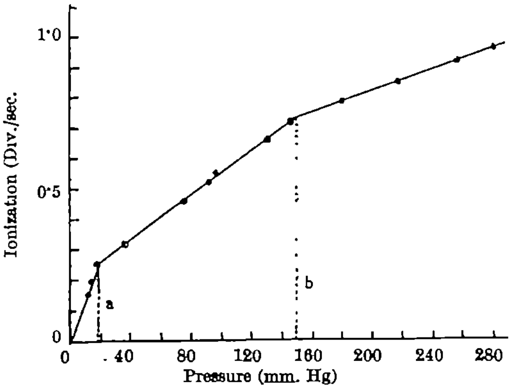

Fig. 1. Ranges of α-particles from samarium. *a* is the new range observed; *b* is the known range of samarium particles.

The curve in Fig. 1 shows the ionization current as a function of the pressure for a film of samarium oxide (Sm_2O_3) of 0·416 mgm./cm.². (A specimen of pure samarium oxide was kindly lent by Prof. G. v. Hevesy to Prof. Wertenstein.) The position of the kink corresponding to the range of α-particles of samarium can be determined with great precision. From this position I find that this range is equal at 760 mm. and 15° to 1·150 cm., in good agreement with the value recently found by R. Hosemann[1].

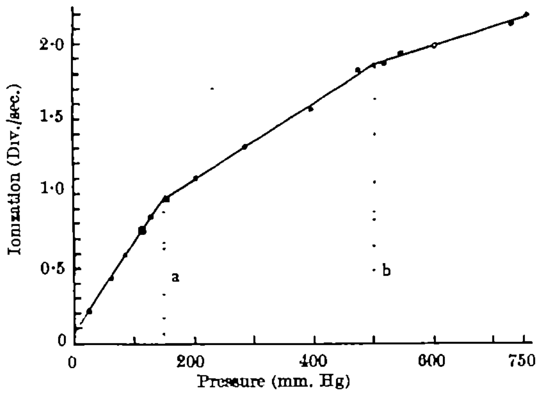

Fig. 2. Ranges of α-particles from samarium and polonium. *a* is the range of particles from samarium, *b* is the known range for particles from polonium.

The curve in Fig. 2 was obtained with a film of 1·05 mgm./cm.² of samarium oxide to which a very small amount of polonium was added for calibration. The position of the kink due to α-particles of samarium is exactly the same as in Fig. 1, while the range of α-particles of polonium I find to be 3·907 cm., in excellent agreement with recent data.

The interesting fact is that the curve in Fig. 1 shows also another kink, clearly indicating the existence of ionizing particles of much shorter range, namely, 0·13 cm. The existence of these particles is also confirmed by the fact that the straight line continuation of the curve in Fig. 2 does not pass through the origin of co-ordinates but above it.

The total ionization due to these particles is equal to about 35 per cent of the total ionization due to α-particles, which makes it highly improbable that the particles of short range should be recoil atoms of any element formed during the disintegration of samarium. No adequate explanation of the nature and origin of these particles has so far been found, and further experiments are in progress.

Absorption of Thermal Neutrons in Silver at Low Temperatures

We have measured the absorption curves for neutrons of Fermi's[1] group 'C' using a silver target (2·3 min. activity) as detector, in the centre of a large Dewar vessel containing either liquid hydrogen or water at room temperature. Source, absorber and target were kept at room temperature. The intensity of the *C* group was determined in the usual way by taking the difference between the whole activity and that obtained by screening the target with 0·3 mm. cadmium. If a Maxwellian distribution for the energies of neutrons of this group be assumed, and if the $1/v$ absorption law predicted by theory is valid for silver, the ratio of the absorber thickness necessary for equal absorption at different temperatures would be expected to be independent of the absorption itself and to be equal to the square root of the inverse ratio of the temperatures. Experimentally we found that this ratio for 290° K. and 20·4° K. is in fact constant over the whole of the absorption curves; its value, however, was found to be 2·2 ± 0·2, instead of 3·8 to be expected from the $\sqrt{T_2}/\sqrt{T_1}$ hypothesis. One of the silver absorbers was measured also at 77° K. in paraffin and the ratio of thickness was also in this case considerably smaller than that given by the theory, the point being nearer to 290° K. than to the 20·4° K. curve. The results of the measurements are given in the table below.

Temperature (Kelvin)	Thickness of absorber mm.	Thickness of absorber gm./cm.²	Transmission for C-neutrons per cent
20·4°	0·26 0·50 0·64 2·0 3·0	0·0273 0·0525 0·0672 0·210 0·315	58·5 ± 3·8 48·1 ± 2·5 40·0 ± 2·0 15·3 ± 2·2 9·4 ± 3·6
77°	0·64	0·0672	57·5 ± 2·8
290°	0·64 2·0 3·0	0·0672 0·210 0·315	68·8 ± 2·0 31·4 ± 4·4 22·2 ± 1·2

We must conclude, therefore, that at low temperatures either the energy distribution of neutrons in the C group is not given by Maxwell's law or the $1/v$ law does not hold for the absorption of C neutrons in silver, using the second period as detector.

Cross Linkage Formation in Keratins

OWING to the breakdown of salt and sulphur linkages, and consequent rearrangement of the peptide chains, untreated wool fibres contract 30 per cent in length in boiling sodium bisulphite solution, whereas fibres containing stable linkages between the peptide chains fail to contract under similar conditions[1]. This fact has been used to show that baryta-treated fibres contain —S—Ba—S— bonds[2], and set fibres contain —S—NH— bonds[3] between the peptide chains. In addition, since caustic soda-treated fibres fail to contract in sodium bisulphite solution, it was suggested that $-\overset{|}{\underset{|}{C}}-S-\overset{|}{\underset{|}{C}}-$ bonds are formed by the action of caustic soda on the cystine linkage, thus explaining why skins are more difficult to unhair after treatment with alkali[4]. In support of this view, it was pointed out that Harris had failed to reduce the sulphur content of wool fibres to less than half its original value by caustic soda treatment[5], and that Küster and Irion had isolated a $-\overset{|}{\underset{|}{C}}-S-\overset{|}{\underset{|}{C}}-$ derivative from the products of the action of sodium sulphide on wool[6]. More recently, Harris[7], taking advantage of the work of Zincke and Farr[8], and of Schöberl[9], has shown that aldehyde groups are produced by loss of hydrogen sulphide from the sulphenic acid derived from the disulphide bond by alkaline hydrolysis, and Phillips[10] has suggested that the aldehydes may condense with the basic side chains of wool to produce —N=CH— bonds between the peptide chains.

This suggestion appears to be valid, because caustic soda-treated fibres, which fail to contract in boiling sodium bisulphite solution, contract after being subjected to treatments calculated to break —N=CH— bonds. For example, caustic soda-treated fibres, boiled in $N/5$ hydrochloric acid for 30 minutes, contracted 16 per cent in boiling 5 per cent sodium bisulphite solution; and treated fibres boiled in $N/10$ pyruvic acid for 1 hour contracted 14 per cent under similar conditions[11]. It seems probable, therefore, that —N=CH— bonds are present in caustic soda-treated fibres, although the incompleteness of the contraction implies that other types of bond are present, possibly the $-\overset{|}{\underset{|}{C}}-S-\overset{|}{\underset{|}{C}}-$ bond first mentioned in this connexion.

Although Phillips makes no such suggestion in his note[10], it might be assumed that the new linkages formed in 'setting' stretched fibres in steam are —N=CH— in type, rather than the —S—NH— bonds first postulated. This does not seem to be the case, because fibres set in boiling 2 per cent borax solution fail to contract in boiling $N/5$ hydrochloric acid or $N/10$ pyruvic acid. Not only so, but the fibres boiled in $N/5$ hydrochloric acid retain a set even in boiling sodium bisulphite solution. Similarly, if permanent set were due to the formation of —N=CH— bonds, the response of fibres to setting processes should be increased by pretreatment with alkalis to develop aldehyde groups. In actual fact, setting power decreases steadily with increasing time of treatment with alkali, the amount of permanent set being a linear function of sulphur content in the case of baryta-treated fibres. These and other observations, which will be described elsewhere, find a ready explanation in terms of —S—NH— bond formation in setting processes, but no explanation in terms of the —N=CH— bond.

Effect of Dichlor-diethyl-sulphone on Brain Respiration

MY colleagues and I have been developing recently the theory that vitamin B_1 is a specific factor in the oxidation system of pyruvic acid. In a search for substances which would inhibit specifically this action of vitamin B_1 in its relation to the pyruvate oxidase of brain, I tried ten months ago the effect of dichlor-diethyl-sulphone $(Cl.CH_2.CH_2)_2\ S.O_2$, for a specimen of which I am indebted to Dr. E. Walker. I am encouraged to communicate the results by the recent publication of Berenblum, Kendall and Orr[1], who state that D.E.S. with tumour tissue inhibits respiration some 50 per cent and glycolysis some 84 per cent. I have found that the action of D.E.S. upon our brain respiration systems *in vitro* resembles in detail the effect of iodoacetic acid[2]; the significant points are as follow:

Noticeable effects upon respiration in lactate Ringer phosphate solutions are produced by so little as 0·000087 M. (up to 50 per cent inhibition) D.E.S. With 0·000174 M. (similar concentration for iodoacetic acid, 0·005 M. approx.) and our usual technique, pyruvate is not oxidized, but accumulates from normal respiring brain tissue in presence of lactate. Hence at this concentration in the reactions

$$\text{Lactate} \underset{C}{\rightarrow} \text{Pyruvate} \overset{\begin{array}{l}\text{D.E.S.}\\ \downarrow \text{ iodoacetic acid}\end{array}}{\underset{D}{\rightarrow}} \text{oxidation products}$$

there is no appreciable effect upon step C, but only upon D. Lack of vitamin B_1 also affects stage D, but as with iodoacetic acid, the action is not upon the vitamin B_1 component. Addition of excess vitamin B_1 will not restore the action with normal brain tissues, nor is the toxic effect removed by addition of glutathione (GSH), provided that time has elapsed to permit complete action of the D.E.S., which is rather slow (it needs some 30 min. at 38° C., pH 7·3). Further proof that the vitamin B_1 component is not involved lies in the following: Vitamin B_1 incubated for 35 min. at 38° C. with D.E.S. in excess (pH 7·3) can be proved to be still active by detoxicating the excess D.E.S. present with GSH and testing the solution so formed.

The similarity in action of iodoacetic acid and D.E.S. upon the pyruvate oxidase system is of interest in relation to the similar vesicant action of these compounds, and possibly of interest in tumour research.

A Hardness Tester for Microscopical Objects

INCLUSIONS and structural elements of metallographic specimens can be identified by examining the effect of various etching reagents. This method not only takes up a great deal of time, but also demands considerable experience on the part of the examiner.

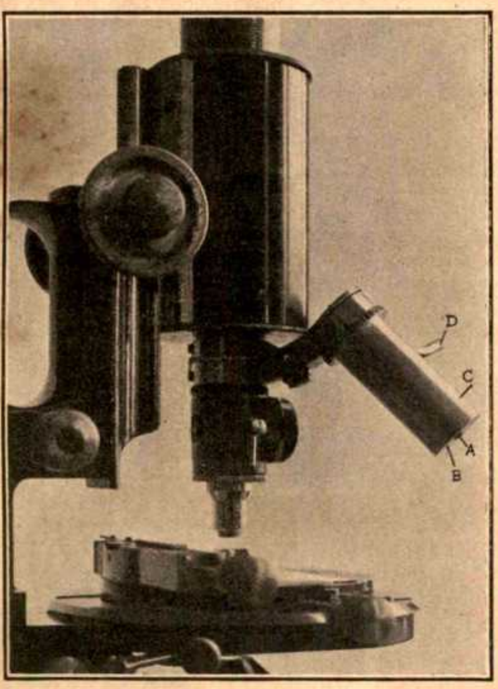

FIG. 1.

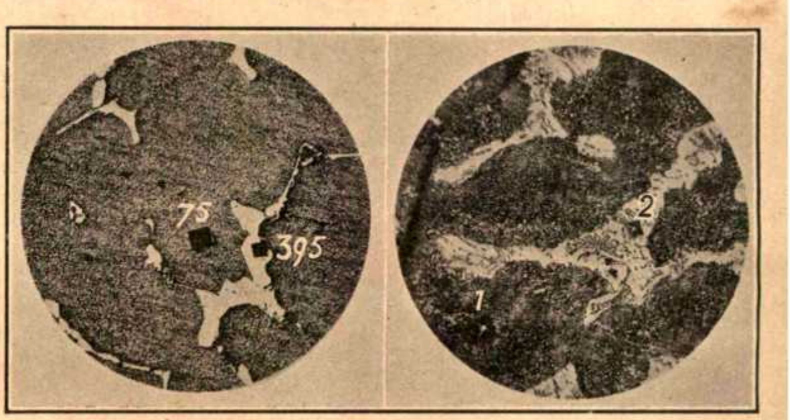
A more convenient and objective identification can be obtained by measuring the hardness of the inclusions and structure elements themselves. Instead of using the scratch hardness tester, which offers considerable difficulties[1], we have designed for this purpose a small and simple instrument, the basic principle of which corresponds exactly with that of the hardness testers of Vickers and of Firth. Fig. 1 shows the instrument mounted in the revolving head of a microscope with a vertical illuminator. The hardness tester consists of a Vickers' diamond A with a pyramid-shaped point, which is fixed in a piston B. The piston, having a certain weight, can move freely in a cylinder C.



(*a*) (*b*)

FIG. 2. Micrographs of (*a*) cast aluminium alloy containing 7·5 per cent copper (× 150); (*b*) pearlitic cast iron containing 0·8 per cent phosphorus (× 300).

The hardness, for example, of an inclusion or of a structural element, is tested in the following manner. The element to be tested is brought into the centre of the field of vision. Then, by turning the revolving head, the hardness tester is brought into the optical axis of the microscope. The tube of the microscope is moved downwards to such an extent that the diamond rests on the specimen and makes a small square impression in the structural element. After a certain time (for example, 30 sec.) the tube of the microscope is again moved upwards and the revolving head turned through 180°. By means of an ocular micrometer, the length of the diagonal of the square is measured, which can be expressed in Vickers numerals in the usual manner.

Fig. 2 (*a*) is a micrograph of a cast aluminium alloy containing 7·5 per cent of copper. The impressions caused by the diamond are clearly visible. The corresponding hardness numerals have been inserted in the figure.

Fig. 2 (*b*) is a micrograph of pearlitic cast iron, containing 0·8 per cent of phosphorus. The diamond impressions in the pearlite and the phosphide eutectic are marked 1 and 2 respectively. The corresponding hardnesses are 395 and 775 respectively. The Vickers hardness $V/20$ was 243.

In the case of malleable cast iron, the hardness of the ferrite was 182, that of the pearlite 300. For martensite a hardness of 865 was measured, whilst cementite showed a hardness of 820.

In the examples mentioned above, the load of the diamond is equal to the weight of the piston, namely, 35 grams. It is, however, possible to use arbitrary loads by means of air pressure above the piston. For this purpose an air inlet D is fitted to the cylinder C (Fig. 1). In this way the instrument can be applied to normal metallographic microscopes. A further advantage of the apparatus described is that it can be used during ordinary examination of metallographic specimens.

Measurements of Noise

THOSE interested in noise measurement will be aware that a new unit of equivalent loudness, the British Standard Phon, has been introduced by the British Standards Institution (Glossary of Acoustical Terms and Definitions B.S. 661—1936). The standard of reference is a plane sound wave of 1,000 cycles per sec., heard alternately with the noise to be measured by an observer facing the source and listening with both ears. When the reference tone is judged by a 'normal observer' to be as loud as the noise, the equivalent loudness in phons is given by the intensity level of the reference tone above a reference pressure of 0·0002 dyne per sq. cm. The experimental realization of the definition requires the resources of a laboratory, so that it becomes of interest to inquire how far the indications of portable secondary meters used for measurements in the field conform to the standard.

Many subjective secondary meters developed before the formulation of the standard, including one developed by us, operate by the observer listening simultaneously to the noise with one ear and a pure reference tone, presented by a telephone receiver, with the other. The reference tone is then adjusted by trial to loudness equality with the noise, the magnitude of which is expressed as the intensity of the reference tone in decibels above a stated reference intensity. In view of the disparity in listening conditions, it is important to ascertain whether the meter indications conform to the standard. We have carried out measurements, in accordance with the definition, of the equivalent loudness of noises of many types with a group of ten observers, such noises being also measured by the same group using a subjective meter of the type indicated above. It is found that with an instrument adjusted to read correctly for 1,000 cycle high-intensity tones, there are discrepancies of varying amounts up to + 15 db., depending upon the type of noise. For some purposes a correction of − 6 db. to the reading brings the indications sufficiently near to the standard.

A mode of listening approximating more to the definition is made possible by using a meter with two receivers. If suitable sealing is provided, the noise and reference tone may be heard alternately by quickly removing or replacing the receivers on the ears. The reference tone intensity is adjusted by trial until no loudness change is heard on removing or replacing the receivers. Tests with a meter constructed on these lines and calibrated in a 1,000 cycle free field show that for a variety of types of noise from 30 to 95 phons, the true value is given on an average to ± 2·5 phons, the largest discrepancy in mean reading noted being 4 phons.

A meter of this type thus enables the measurement outside the laboratory of any type of steady noise in phons. It has been used for measuring the noise of large engineering plant and has been found more trustworthy than the single-telephone method. The two-telephone meter also forms a link between the plane field distribution of the phon definition and the irregular field distributions which may occur in practice. Such an irregular sound field is thereby assessed in terms of the intensity level of the 1,000 cycle plane wave which, for a 'normal observer', produces an equal loudness sensation. Thus the pronounced directional properties of some microphones, which may have an arbitrary effect in objective noise measurements, may be eliminated.

The performance of secondary meters in terms of the phon will be discussed in a paper which it is hoped to publish in the near future.

Influence of Temperature on Crossing-over in *Drosophila*

ALTHOUGH it has now been demonstrated by several workers that crossing-over in certain regions of the chromosomes of *Drosophila melanogaster* is affected by temperature, the experiment reported in Table 8 of Plough's classical paper[1] still remains the only attempt to trace the magnitude of the effect throughout the range of temperature over which *Drosophila* is fertile. Unfortunately, when correcting the data for differences among the controls, a mistake was made which led to the false conclusion that crossing-over showed two maxima, at 13° and at 31° C. The *b–pr–c* region of chromosome II was used for the experiment. The observed percentages of crossing-over between *b* and *pr* are reproduced in the table below:

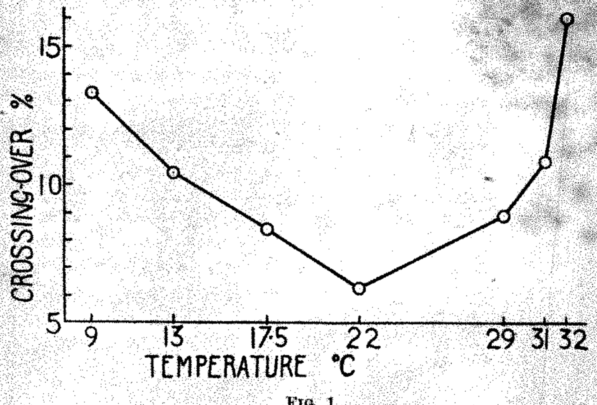

FIG. 1.

Table 1.—Crossing-over between *b* and *pr*. (Data from Plough's Table 8).

Temperature °C.	Observed per cent	Control at 22° C.	Corrected values, that is, 6·0 (Observed)/Control
9	13·5	6·1	13·3
13	13·5	7·8	10·4
17·5	8·3	5·9	8·4
22	6·0	—	6·0
29	8·8	5·9	8·9
31	14·0	7·8	10·8
32	15·7	5·9	16·0

When corrections for the controls are properly applied the relation between crossing-over and temperature is seen to conform to a simple *U* curve (Fig. 1).

This mistake came to my notice in 1927, but having no first-hand interest I was content to communicate the error to colleagues more specifically interested in genetics of *Drosophila*. It has recently, however, been brought to my notice that the mistake is still a source of trouble. Besides having been reproduced in a number of text-books, the supposed maximum at 13° is of some importance in correlating these data with observations on the effect of temperature both on contraction of muscles (Plough[1]) and on chiasma frequency in *Acridiidæ* (White[2]).

Tetraploidy and Hymenoptera

A COMMUNICATION[1] from B. R. Speicher has directed attention to certain genetical data which do not seem to favour my suggestion[2] that the 'pre-conjugation' phenomena observed in the gametogenesis of the honey bee and of *Cynips kollari* may be interpreted in terms of derived tetraploidy. Now while I admit that the findings of the experiments of Dzierzon, Michailoff and Newell, as quoted in Mr. Speicher's letter, do suggest a simple condition of female diploidy and male haploidy, the facts are by no means fatal to a theory of derived tetraploidy–diploidy based on cytological observations. It has recently been shown that tetraploid hybrids do not necessarily exhibit independent segregation of chromosomes in gametogenesis and also that gametic viability in these forms is often differential, and only those gametes carrying one complete genom or the other are functional. It is thus possible for an organism to behave *genetically* as a diploid while in its gametogenesis traces of a different cytological condition may be shown. Genetical methods, therefore, may not be infallible criteria of evolution.

In this connexion, it should be observed that, in my original communication, the phenomena under discussion were regarded as vestiges in the evolutionary sense. At the same time it may be noted that there is probably conflict in the use of the terms tetraploidy, diploidy and haploidy, as employed by geneticists and by cytologists.

Refractive Indexes of Ordinary and Heavy Ammonia

MEASUREMENTS of the refractive index of light and heavy ammonia were performed in continuation of former investigations[1]. The interferometer and the experimental arrangements were the same as before with the exception that this time one tube was made of glass and the other of quartz. A discharge tube containing hydrogen, a mercury lamp and a sodium lamp served as sources of light. The spectral lines in question were separated out by means of a monochromator from Winkel-Zeiss.

NH_3 (or ND_3) were produced by adding ordinary water drop by drop (or heavy water, 99 per cent, from Norsk Hydro-Elektrisk Kvælstofaktieselskab) to magnesium nitride. The drying and purification of the gas were performed in a manner similar to that described in the paper dealing with ordinary and heavy hydrogen selenide. The pressure of the gas was between 25 cm. and 28 cm. of mercury, the temperatures between 15° and 20° C. The reduction of the refractive index to the normal conditions and the state of an ideal gas was performed by using the coefficient of dilatation at constant pressure:

$$\alpha_{15,H} = 0{\cdot}00366 + 0{\cdot}000182\,\frac{H}{76}.$$

For the quantity φ which gives the deviation from Boyle's law the value 0·015 was used from the "International Critical Tables".

The results of the measurements are to be found in the accompanying table.

$(n_0 \div 1) \times 10^6$.

$\lambda \times 10^8$ cm.	6562·9	5893	5461	4916	4358
NH_3	373·6	375·7	377·7	381·4	386·3
ND_3	369·4	372·6	374·1	378·2	383·3
Δ	4·2	3·1	3·6	3·2	3·0

The refractive indexes of NH_3 are in good agreement with the measurements of C. Cuthbertson[2], while the measurements of S. Friberg[3] and E. W. Cheney[4] are perceptibly higher.

The method used by the measurements of NH_3 and ND_3 being completely consistent, the differences found between $n_{0,\,NH_3}$ and $n_{0,\,ND_3}$ are to be regarded as real in all circumstances.

Range of Action of Surface Forces

THE letter by Bowden and Bastow, published in NATURE[1] (as well as their communication to the Royal Society[2]), not only may give, but already has given, rise to the view that the rigidity of thin water films observed by myself has not been confirmed by the above authors[3].

A thorough discussion and comparison of Bowden and Bastow's data with mine renders it manifest, however, that there is no contradiction between our respective results. Indeed, it has been shown by my data that the rigidity of water is exhibited when the thickness of the film is less than $1\cdot5 \times 10^{-5}$ cm., that is, at a distance less than $0\cdot75 \times 10^{-5}$ cm. from the glass surface. Rigidity equal to that of lead has been observed in my experiments for distances of $0\cdot5 \times 0\cdot7 \times 10^{-5} = 0\cdot35 \times 10^{-5}$ cm. from the walls.

In accord with the subsequent measurements of Bowden and Bastow, my measurements have, therefore, refuted the indications of the existence of rigid films of liquids of considerably greater thickness to be found in other papers, among them in those by the late Sir William Hardy. The only difference lies in the fact that my measurements have established a smaller and at the same time a more accurate upper limit of the range of surface action for the case of a glass-water interface.

It only follows from Bowden and Bastow's experiments that the range of surface action modifying the mechanical properties of a liquid film does not exceed 2×10^{-5} cm. for a glass surface, the liquid films in their experiments being located between a glass surface and a metal one, that is, one of another kind, and, moreover, a hydrophobic one. More than this, the data given in Table I of their Royal Society paper show that the thickness of the mobile part of the liquid is on the average *less* by 2×10^{-5} cm. than the optically determined thickness of the gap between the solid surfaces. Although no great weight can be attached to the latter positive result, it shows that there is no question of Bastow and Bowden's data refuting my experiments.

Effect of Molecular Nitrogen on Molybdenum at High Temperatures

TREATING molybdenum wires of 0·2 mm. in a stationary manner by passing electric current through them and testing the behaviour of the wires under tensile stress, we have found that specimens heated in nitrogen are of quite a different character from those treated in hydrogen, argon or *in vacuo*. The yield point (in general, at the yield point of the wire plastic deformation of the metal commences) and the elongation of the wire in particular are very markedly influenced by nitrogen. Fig. 1 shows the load-extension curves of wires treated in nitrogen, the arrows indicating the yield point of the wire.

The following are the chief points of interest obtained in the course of our experiments. Different pre-treatments of wires exert an appreciable influence on the rate of nitriding. Thus cold-worked wires react much more slowly with nitrogen than they do if they are annealed, whilst the reaction is the slowest of all if the wires are fully recrystallized. In the later case, the characteristic stage represented in Fig. 1, No. 4, cannot be reached at all.

If nitrided wires (Fig. 1, No. 4) are permanently deformed, say, by being bent on little pulleys, they regain fully the original normal properties (Fig. 1, No. 1) which they possessed prior to nitriding. It seems possible that the failure to detect hitherto the effect of nitrogen on molybdenum wires is due to this peculiar fact. But nitrided wires after being bent revert again to their 'nitrided' stage (Fig. 1, No. 4) if they are flashed even in argon for 1–2 sec.

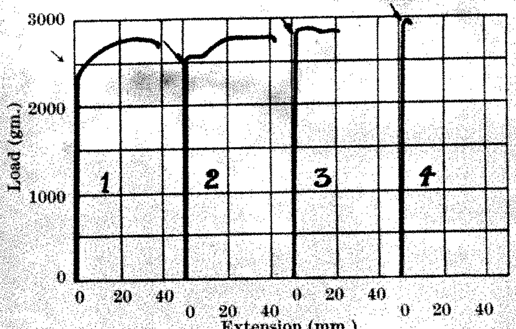

FIG. 1. (1) Wire treated at 1400° C. for 2 min. only in hydrogen. (2), (3) and (4). Wire pre-treated as (1) and then at 1300° C. for 20 sec., 40 sec. and 1 min. respectively in nitrogen.

On nitriding, no changes in the electrical resistivity was observed. The quantity of nitrogen sorbed corresponding to the stage of No. 4 in Fig. 1 is not more than about 0·007 per cent[1]. If nitrided wires are heated in hydrogen or *in vacuo*, denitriding takes place. Both contamination of the surface of the wire by carbon and minute traces of oxygen or/and water-vapour present in the gas retard the penetration of nitrogen into the wire.

Our observations appear to be of interest in relation both to the nature of plastic deformation of metals in general and to that of the catalytic action of molybdenum on ammonia synthesis[2].

We hope to publish fuller data elsewhere at a later date.

Flora of the Canadian Eastern Arctic

IN preparing a flora of the northernmost regions of eastern North America, nowadays generally referred to as the "Canadian Eastern Arctic", I am attempting to gather together, revise and record fully all of the more substantial plant collections that have been made within the area concerned from the times of the earliest navigators and pioneer explorers to the present day. This area for the present purpose is to be defined as excluding Greenland, Ellesmere (the flora of which is well known) and Boothia Felix, but otherwise as comprising all the mainland of eastern North America that lies east of long. 95° W. and north of lat. 60° N., and all the islands of the arctic archipelago (including the 1,000-miles long Baffin Land) that lie either wholly or in part within these bounds.

Since a number of collections have already come to light in unexpected places, I am taking the liberty of asking you, through the medium of your widely read correspondence columns, kindly to make known my great desire to hear of any further collections from within this area that I have not already seen in North America or shall not be likely to see in visiting the main European herbaria. I am now returning to the field with the Canadian Eastern Arctic Patrol to gather further material; from this or my other collections I should be pleased to make a presentation of duplicate specimens of high arctic plants in return for the courtesy of any loans of older collections that prove of interest.

The Mysterious Number 137

In Nature of July 11, Sir Flinders Petrie points out that Sir Arthur Eddington's cosmical number, 137, is nearly the well-known 'Byrne's' number, 137129, the mantissa of the logarithm of which shows the *same succession of digits*. It is sometimes said to be the number which is equal to its logarithm; but actually of the number 137·129 . . we should say that one thousandth of the number is the logarithm, to base 10, of one hundredth of the number. This coincidence between Eddington's and Byrne's numbers can have no physical significance, because the coincidence depends on 10 being used for the scale of notation and the base of the logarithms. The older wisdom of Mars may have adopted scales and bases of twelve; if so, the Martian Eddington would have discovered the number $e5$ ($11 \times 12 + 5 = 137$), while the Martian Byrne would have shown that log (to base twelve) $1{\cdot}38e66 = 0{\cdot}138e66$. Raising this number two duodecimal places, we have $138{\cdot}e66$, in the scale of twelve, which equals 188·961 in our notation.

Other such Byrne type numbers can be found in all scales of notation, and they are all different. For example, in the scale and base of three, the Byrne number is 2110220, and 211·022 (in scale of three) only equals 22·296 in our notation.

Points from Foregoing Letters

Graphs showing the average hourly intensity of cosmic rays at Cape Town for the years 1933, 1934 and 1935 are submitted by Dr. B. F. J. Schonland, B. Delatizky and J. P. Gaskell. A slight sinusoidal variation is apparent, with a maximum at about 24 hr. local sidereal time and a minimum at 12 hr. The variation appears to be a true sidereal time effect, since it occurs simultaneously in both hemispheres.

Measurements of cosmic ray intensity in a deep coal mine, carried out by Drs. J. Barnóthy and M. Fórro, indicate that some of the rays penetrate through a thickness equivalent to 2,500 m. of water. These would correspond to particles having an energy greater than 10^{12} electron volts.

New measurements by L. Lewin of the range of particles emitted by samarium show, in addition to the alpha-particles of 1·15 cm. range, also the presence of ionizing particles of 0·13 cm. range, amounting to about one third the total ionization due to alpha-particles.

The absorption by silver of 'thermal' neutrons at low temperatures (20·4° and 77° K.) has been determined by a group of investigators from the Ukrainian Physico-Technical Institute. They find that the ratio of the absorber thickness necessary for equal absorption at different temperatures, though constant, has a value of only about two thirds that to be expected if the absorption were inversely proportional to the velocity and a Maxwellian distribution for the energies of the neutrons be assumed.

The nature of the chemical linkages responsible for the contraction of wool when treated by various reagents is discussed by Dr. J. B. Speakman. He considers that the 'permanent set' is to be explained by the formation of —S—NH— bonds rather than in terms of —N=CH— bonds.

Prof. R. A. Peters describes the effect of dichlordiethyl-sulphone upon the respiration of brain tissue *in vitro*. As in the case of iodoacetic acid, there is no interference with the change of lactic to pyruvic acid, but the further oxidation of pyruvic acid is inhibited.

An instrument for testing the hardness of microscopic objects is described by Dr. E. M. H. Lips and J. Sack, who submit photomicrographs of copper-aluminium alloy and of cast iron containing phosphorus to illustrate the usefulness of the new apparatus.

Results of noise measurements made with earlier types of meters are compared by B. G. Churcher and A. J. King with values obtained by means of the new standard apparatus. The authors indicate conditions under which approximately equivalent results can be obtained.

H. F. Smith recalculates the percentage 'crossing-over' effect in the chromosomes of the fruit-fly at different temperatures, from the experimental results of Plough, allowing for differences among the controls. He points out that the graph has a U-shaped form with a minimum at 22° C., and that there are no maxima at 13° and 31° as sometimes stated.

The refractive indexes of ordinary and of heavy ammonia gas (ND_3) for various wave-lengths between 4358 and $6562{\cdot}9 \times 10^{-8}$ cm. have been determined by O. E. Frivold, Prof. O. Hassel and S. Rustad. The values for the heavy ammonia are slightly lower than those for ordinary ammonia.

Dr. B. Derjaguin directs attention to the fact that there is no disagreement between his findings that films of water of less than $1{\cdot}5 \times 10^{-5}$ cm. thickness have great rigidity, and the results of Bowden and Bastow, who have found no change from normal behaviour at thicknesses greater than 2×10^{-5} cm.

Diagrams showing the hardening of molybdenum wires heated in nitrogen at 1300° C. (by passing an electric current) are submitted by P. Túry and S. Krausz. The quantity of nitrogen 'sorbed' by the molybdenum is small (about 0·007 per cent).

Research Items

Tuberculosis and Inheritance

As part of the laboratory work in connexion with a course in human biology in Johns Hopkins University, Baltimore, Prof. Raymond Pearl initiated a study of family history records with reference to families in which tuberculosis had occurred. Analysis and discussion of the data have elicited some interesting results (*Z. Rassenkunde*, **3**, 3). The records examined include 3,608 individuals in the classification of parents and children. Taking all the offspring together, 11·3 per cent were tuberculous, which is in reasonable agreement with the known prevalence of tuberculosis in Baltimore at the time the records were taken. The families average between 4 and 4·6 children. Four types of mating were differentiated and the percentage of tuberculous offspring in each type noted. There were : Both parents tuberculous, 35·7 per cent ; father tuberculous, 14·0 per cent ; mother tuberculous, 13·0 per cent ; neither parent tuberculous, 8·3 per cent. The smoothness and regularity of the results are noteworthy. The incidence in the non-tuberculous parentage is a little more than half that of the tuberculous – non-tuberculous mating. The rates of the two latter types are essentially in agreement, as might be expected theoretically, if it is assumed that tuberculosis is neither a sex-linked nor a sex-limited phenomenon. Further, the full tuberculous mating gives an offspring incidence a little more than four times that from the full non-tuberculous mating. The regular increase in the offspring percentage incidence, as the amount of parental tuberculosis increases, seems impossible of rational explanation on any other basis than that of hereditary influence, as the risk of contact infection is not quantitatively doubled. The risk of infection as between the children of tuberculous and non-tuberculous parentage would seem greater than is indicated by the figures. It seems impossible, with the data at present available, to postulate any simple rational Mendelian formula that will accurately describe the results.

Archæology in Western Colombia

In 1935 Dr. Henry Wassén had the opportunity of examining a number of graves belonging to an ancient Indian settlement on the estate of El Dorado in the western Colombian Cordilleras, midway between Yotoco and Rostrepo in the Department of Valle del Cauca (*Ethnologiska Studien*, 1936, No. 2 : Göteborg Museum). Among the objects found in the neighbourhood described, but not found by the author, are two vessels painted in red-brown, of a characteristic shape, the neck rising from a horizontal plane. Three strong handles, adapted for carrying the vessel on the back, are at different levels. This arrangement does not appear to have been recorded previously among archæological finds in South America, but can be paralleled from Mexico. Further examples were obtained from the graves. Nine graves in all were opened up on four different sites. The type form is a shaft, oblong in section, the long sides orientated north and south, with a recess, or chamber, usually on the north, but here on the south side, elliptical or rectangular in shape. The shaft is here four to six metres deep, between one and two metres long, and approximating to a metre in breadth Examples have been recorded in which the shaft is 14–17 metres deep (Cauca) and even so much as 25 metres (Quinidio). The elliptical recess, with its long axis east and west, approximates to a metre in height, two to two and a half metres long and from 0·75 to 1·35 m. in breadth. One recess was a rectangular chamber of considerable size. In one group the recess was scarcely perceptible and not deep-seated. One grave had no recess. Another grave of a distinct type had a square shaft, 6·10 m. deep, with the chamber below the level of the bottom of the shaft, the entrance to the recess being closed by a grinding stone. This had evidently contained the body of a woman, as was shown by spindle whorls. A hair ornament in the form of nippers and a part of a nose ornament, as well as the position of the teeth, indicated that the head had been placed to the north. On analysis the nose ornament proved to be composed of gold (64 per cent), silver (9 per cent) and copper (27 per cent). Green stain on the teeth indicated the presence of copper. The skeletons had completely perished, except for a few fragments and some teeth.

The Medusæ *Eirene* and *Helgicirrha*

Dr. P. L. Kramp clears up much confusion in his paper "On the Leptomedusæ of the Genera *Eirene* Eschscholtz and *Helgicirrha* Hartlaub" (*Vidensk. Medd. fra Dansk naturh. Foren.*, **99** ; 1936). True cirrhi are absent in *Eirene* but present in *Helgicirrha*, and on this character the genera may be divided. Twelve species of *Eirene* are distinguished here, and five or six species of *Helgicirrha*, the genotypes being *Eirene viridula* and *Helgicirrha schulzei*. A re-examination of material previously identified by the author as *Eirene viridula* shows that specimens from the coast of Belgium and the Straits of Dover (1930) are correctly identified, but the majority of those from the coast of Jutland (1927) belong to *Helgicirrha schulzei*, a few being *Eirene viridula* ; those from the Straits of Gibraltar and the coast of Tunis (1924) are *Helgicirrha schulzei*, and those from the coast of Portugal (1910) are *Helgicirrha cari*.

Sponges of the North Sea and Baltic

Dr. W. Arndt in his monograph Porifera (Systematische Teil) in "Die Tierwelt der Nord- und Ostsee", Lief. 27, Teil $3a_1$ (Leipzig : Akademische Verlagsgesellschaft m.b.H., 1935) makes a very complete systematic survey of the sponges in these regions. There is a large sponge fauna to be found in the North Sea and Baltic, including representatives of many families. These are all described in detail, with good text figures, whilst useful keys of families, genera and species are given, with instructions for technique for studying living and preserved material, and an excellent bibliography. This most useful work on the fauna of the North Sea and Baltic keeps well up to standard in the present part, which also includes an interesting account of Thalassobionte und thalassophile Diptera Nematocera (Teil 11, e_3) by W. Hennig.

Experimental Neoplasms

THE developing blastoderms of birds and reptiles occasionally exhibit, in the region of the primitive streak, proliferating masses of cells which, while they multiply freely, show no tendency to transform into embryos or embryonic structures. These pathological masses grow with considerable rapidity and exhibit all the characters of neoplasms, and for that reason they have been termed by Tur "neoplasmoides embryonnaires". This author has produced the same type of growth experimentally by means of a thermoelectric cautery (*Bull. Int. Acad. Polonaise*, July 1935). The platinum needle, which becomes white hot, is carried by a mechanism which enables it to be applied accurately to any given point on or near the blastoderm, and also to apply the heat for a definite period. It also allows the heat to be controlled without the loss that would take place in manipulating a heated needle through the albumen layer. After treatment, the aperture in the egg shell is sealed with a cover slip and incubation allowed to proceed. Freshly laid eggs are employed, and the heat applied to the centre of the area pellucida. In this manner, a neoplasm can practically always be produced, and like those occurring naturally they not only exhibit remarkable power of proliferation but also blood elements appear precociously. The author suggests that this phenomenon should be considered in relation to cancer.

Haploids in Cotton

SEA ISLAND cotton produces haploids—known as 'man cotton'—in the proportion of one in three or four thousand plants. This type was described by Dr. S. C. Harland in 1920, but its haploid nature was not recognized until much later. By removing the testas of several thousand seeds of one variety, Harland found (*J. Hered.*, **27**, No. 6) that twenty seeds contained two embryos, which yielded in nearly every case one haploid and one diploid seedling. Indian workers have shown that in rice, where a high proportion of haploids also occurs, the same form of polyembryony exists. Such ovules may contain two embryo sacs, or it is possible that the diploid embryo arises from nucellar budding while the haploid develops from a parthenogenetic egg. Many of the cotton haploids are fertile with the pollen of other forms, although some are completely sterile. Harland suggests that if diploids could be produced from the haploids by the decapitation method, the resulting homozygous strains would be of much value in breeding work, especially in cotton, which is a highly heterozygous crop plant.

Control of Downy Mildew of Tobacco

AN interesting method of controlling the fungus disease known as downy mildew, or blue mould, of the tobacco plant, is reported in an account by Science Service from Canberra, Australia. This describes the work of Dr. H. R. Angell, Messrs. J. M. Allan and A. V. Hill, who have shown that early infection can be prevented by raising seedlings in an atmosphere containing vapour of benzol or toluol. Special seed-beds covered with glass have been prepared, and numerous shallow vessels containing the benzol or toluol are placed within. The young seedlings make healthy growth, and when transplanted do not contract the disease. Large-scale field tests are in progress, and their results will be awaited with interest.

The Heat Capacity of Ice

IT has been known for some years that the entropy of ice as given by the integral $\int_0^T C_p \, d\ln T$ does not agree with the value calculated from the entropy of water vapour as found from its band spectrum, there being a discrepancy of about 1 gm.cal. per degree per mol. W. F. Giauque and J. W. Stout (*J. Amer. Chem. Soc.*, **58**, 1144; 1936) have now redetermined the heat capacity of ice from 16·4 to 267·7° abs. The latent heats of fusion and evaporation are accurately known, and the value of the integral is thus found to be $44{\cdot}28 \pm 0{\cdot}05$ gm.cal./1°/mol. at 1 atm. and 298·1° Abs. The spectroscopic value is 45·10, leading to a discrepancy of 0·82. This is in agreement with a discrepancy of 0·806 calculated by Pauling on the assumption of random orientations of hydrogen bonds in ice, and the supposition that when ice is cooled to low temperatures it fails to attain the ordered arrangement which would correspond with zero entropy. It has been found that ice has no measurable heat capacity between 0·2 and 4° Abs., and the authors state that no difference in thermal properties of ice could be detected in samples prepared by slow or rapid cooling.

Manganese Trichloride

ALTHOUGH the existence of a higher chloride of manganese, probably $MnCl_3$, has often been reported, its existence in the pure state has only recently been demonstrated. A. Chrétien and G. Varga (*Bull. Soc. Chim.*, **3**, 1263; 1936) have obtained the trichloride as a brown crystalline mass by acting upon manganic acetate, $Mn(C_2H_3O_2)_3$, with liquid hydrogen chloride at $-100°$. A violent reaction occurs, and an olive-green liquid is produced. This is evaporated to dryness at the same temperature. The solid may be heated to room temperature in a closed vessel with little decomposition. On heating, it evolves chlorine and leaves a white residue of manganous chloride.

Spectra of *B*-Type Stars

Two papers by E. G. Williams on *B*-type stars have appeared recently in the *Astrophysical Journal* (**83**, 279 and 305). The first paper describes the spectrophotometric observations of 84 stars over the range 4922–3820 A. Intensities (expressed in equivalent widths) were obtained for all measurable lines in this range, and in addition line depths were measured for H and He lines. In the case of H and He lines it was also possible to obtain reliable contours, which were observed to be exponential in form except in diffuse-line stars, where the centres were rather blunt. The results of the first paper have been used in the second in an attack on the problem of classification, which presents well-known difficulties in the case of *B*-type stars. These difficulties, together with earlier attempts to overcome them, are first reviewed by the author, who decides that line ratios, rather than simple intensities, are preferable as criteria of classification. He suggests seven ratios, some of which involve the combination of line intensities from several different elements. The resulting classification is arranged to agree in the mean with the Henry Draper system, but with added subdivisions and with the numbers of stars in each subdivision progressing smoothly with type. Statistical relations between spectral type (as redetermined) and line intensities of various atoms are discussed, and some interesting luminosity effects are also obtained.

New Heating Laboratory at the Building Research Station

By A. F. Dufton

> "*In the field of heating and ventilation many phases are still beyond the realm of scientific analysis: as far as possible these topics should be studied for the benefits that might accrue. Scientific methods alone can give us the assurance that we are headed in the right direction, particularly in those departures from standard practice occasionally necessary in everyday application.*"—
> RIETSCHEL, 1893.

PRACTITIONERS in the art of heating are dependent to a great extent upon rules-of-thumb, and are finding, in this age of progress, some difficulty in adapting standard practices and calculations to meet modern requirements. The introduction of panel-heating, for example, has not only made necessary a revision of ideas as to what constitutes a comfortably warmed environment but has brought out also the important fact that the received methods of computing the heat losses of a building are only directly applicable when the building is heated in the 'traditional' manner. The introduction of electric-heating, moreover, particularly of schools, has lent an added interest to the effect of the fabric of a room upon the rate of warming and to the general question of the economics of intermittent heating. The Institution of Heating and Ventilating Engineers, fully appreciating the importance of scientific research, expressed the desire to associate itself as closely as possible with any researches on heating and ventilation under the auspices of the Department of Scientific and Industrial Research, and offered to provide funds to enable this work to be accelerated and extended. With this encouragement, it has now been possible to implement a proposal that a room should be erected with walls, ceiling and floor exposed to controlled conditions, in order to facilitate the study not only of different methods of heating, of the problems of intermittent heating and of the influence of ventilation upon heating, but also of those phases of building construction of interest to heating engineers.

It has been considered a matter of first importance that the controlled conditions should be clearly defined and reproducible, and that they should be independent not only of outside weather conditions but also of the condition of the interior of the room. The idea of a test-room within a controlled enclosure is not new, and a certain number of such rooms have been described and built elsewhere. In each case, however, the controlled conditions have been secured by regulating the air-temperature throughout the enveloping space. This is extremely difficult to accomplish satisfactorily and it does not provide, moreover, a clearly defined enclosure, since it permits of variations in the temperatures of the enclosing walls, to which, of course, the walls of the test-room radiate.

In the heating laboratory which has now been erected at the Building Research Station, Garston (Fig. 1), the temperature of the air in the enclosure is not regulated, and the enclosure is controlled by means of an extensive system of panel-warming and panel-cooling pipes in the walls, floor and ceiling. This enclosure is defined when the temperatures of the various surfaces are specified.

As will be seen from Fig. 2, the heating laboratory comprises the test-room, surrounded by its enclosure, together with an engine-room and an instrument room. The test-room, which measures 18 ft. by 12 ft., is built of 9-in. brickwork, plastered internally, and the floor and ceiling are constructed of wooden joists, lathed and plastered below, and boarded above. The height of the ceiling can be adjusted between the limits of 8 ft. 6 in. and 11 ft. 6 in.

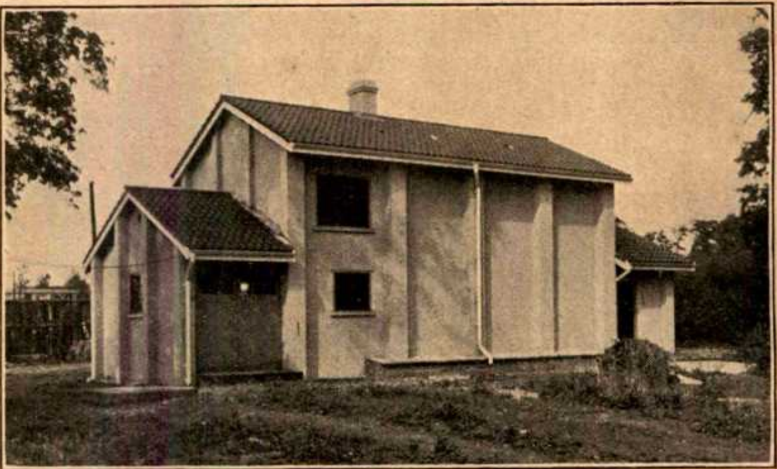

FIG. 1. Heating Laboratory at the Building Research Station, Garston.

The walls of the enclosure are heated or cooled by means of calcium-brine pumped through the embedded pipes which are spaced at 6-in. centres, and their mean surface temperatures are individually controlled to 0·1° F. by copper resistance-thermometers in conjunction with a sensitive relay system. Each wall surface is tested once in every 6 minutes and the controls then automatically raise or lower the temperature of the brine by means of specially designed modulating valves. Each modulating valve is driven by a Warren motor of 10 micro-horse-power.

The modulating valves, which are in the engine room, are fed with hot or cold brine from two insulated storage tanks of 200 and 400 gallons capacity respectively, and the necessary cooling is provided by a 4½-ton ammonia refrigerating plant which is automatic in operation.

Provision is made for the air in the test-room to be changed at rates up to four air changes per hour, with incoming air controlled at 40° F. or other suitable temperature.

In the programme of research which has been under consideration by the Heating and Ventilation Committee of the Department, on which are members of the Institution of Heating and Ventilating Engineers, emphasis has been placed upon the study of the conditions obtaining in a room warmed by extended surface heating and upon the investigation of floor and ceiling heating. It should perhaps be made clear that the new laboratory is specially designed for comparative work, and in the examination of floor heating, for example, it is clearly important to obtain an adequate comparison with other forms of heating. The most common form of central heating in use at the present time is by cast-iron radiators, and it is proposed, therefore, to adopt this as a standard of reference. This will not only provide a very convenient 'yardstick' but will also ensure that a substantial body of data will be obtained relative to this important type of heating.

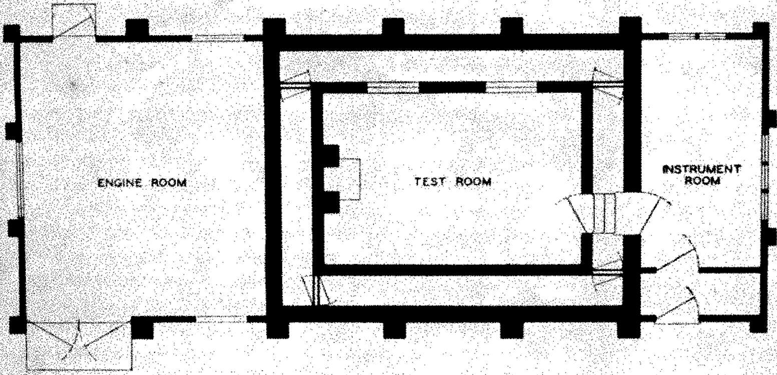

FIG. 2.

The new laboratory was open for inspection on the occasion of the annual visit of the Institution of Heating and Ventilating Engineers on July 22, when the members were received by Sir Raymond Unwin, the chairman of the Building Research Board, and the laboratory was formally opened by Sir Frank Smith, secretary of the Department of Scientific and Industrial Research.

Petroleum Fuels in Canada

DURING recent years, importers and consumers of petroleum fuels in Canada have furnished statistics of deliveries and uses of these products to the Department of Mines. Resulting from correlation of data supplied, a report has been prepared entitled "Petroleum Fuels in Canada" (Department of Mines, Bulletin 772; 1936) from which many interesting facts emerge.

Fuels are divided into four classes: fuel oil, kerosene, gasoline and petroleum coke; after summary tables showing quantities of each marketed in Canada during 1933 and 1934, and amounts distributed in each of the Provinces, the classes are studied separately. In 1934 more than 86 per cent of the total fuel oil was processed in Canadian refineries, the rest being imported; of this, 26 per cent was used for domestic heating, 23 per cent for industrial heating and power, more than 5 per cent for tractor fuel and more than 46 per cent for rail and water transportations. In the same year deliveries of kerosene were less than one eleventh of the volume of fuel oil and represented only one twenty-fifth of the total of petroleum fuels; actually only 36·2 million gallons were delivered in Canada, which is substantially less than was delivered in 1933; approximately 66 per cent of this was used for domestic heating, cooking and lighting, 24·5 per cent for tractor fuel and the remainder for other general uses.

Gasoline statistics included in the report are not strictly comparable with those of fuel oil and kerosene as they represent totals recorded by provincial tax departments of the Bureau and are interpreted subject to provisos as to amounts sold, etc., effective each year in each province. The gallonages supplied under each purpose use are therefore treated as estimates; nevertheless tables showing gasoline sales by provinces and quantities sold for motoring and other purposes are of interest as indication of destination of gasoline marketed in Canada.

Petroleum coke is used primarily as a fuel for domestic and industrial heating but is also a useful component of electric batteries, carbon lamps, crucibles and other manufactured articles; in 1934 approximately 57,000 short tons were sold for fuel, of which about 39,000 tons were destined for domestic heating and 18,000 for industrial heating.

Problems of Translocation in the Plant

MESSRS. Mason, Maskell and Phillis continue their analysis of the movement of substances in the cotton plant in two papers published in the *Annals of Botany* (50, January 1936).

They first give their reasons for rejecting, on present evidence, either the Münch theory of mass flow in the phloem, or the theory of protoplasmic streaming, as providing a satisfactory mechanism for the movements that take place. Any view of mechanism must be influenced by definite information as to whether the phloem can function at the same time to deliver different materials in opposite directions, and these two papers describe the results of experiments designed to elucidate this point. The first paper (by Mason, Maskell and Phillis) shows that whilst very slow import of sugar into darkened leaves is suggested by a formation of starch around the veins of such leaves when they remain in communication with illuminated foliage, yet the behaviour of such darkened leaves isolated by rings as compared with non-isolated leaves does not permit a safe conclusion that sugar may still move in whilst nitrogen moves out. Experiments with defoliated plants with tops in a humid atmosphere suggest that even when transpiration is so reduced, the nitrogen supply of the tops can still be adequately furnished by the xylem. An attempt by suitable ringing technique to demonstrate the movement of stored nitrogen from a basal adult region of the shoot upward into the growing tops when sugars were moving downwards was more promising, but the authors recognize that this stored nitrogen may still have moved down to the roots via the phloem and then upwards via the xylem if the nitrogen is released into the tracheæ in the root.

The later experiment, by Phillis and Mason, is regarded by its authors as giving a more definite answer on the point at issue. The cotton plants in this experiment were all ringed at the base, the basal leaves darkened and one series ringed between the basal region and the apical region. In this case when the plants were starved of all phloem mobile elements, the nitrogen travelled upwards in considerable amount from the basal to the apical region when these were not separated by a ring, whilst little or none entered the apical region when separated by a ring from the basal region.

As carbohydrate was still passing downwards from apical to basal regions in the same plant, these experiments are regarded as supplying good evidence that sugar and nitrogen may travel simultaneously in opposite directions through the phloem.

Science News a Century Ago

The British Association at Bristol

THE work of the British Association at its first Bristol meeting began on Monday, August 22, 1836, there being seven sections, namely, Mathematical and Physical Science, Chemistry and Mineralogy, Geology and Geography, Zoology and Botany, Medicine, Statistics and Mechanical Science. Among the contributors of papers were Brewster, Baily, Lubbock, Whewell, Hamilton, Babbage, Sedgwick, Buckland, Conybeare, Daubeny, Murchison, Dr. Hare of Philadelphia, Lardner, Snow Harris and Scott Russell.

The general meeting of the Association was held on the evening of August 22 in the Theatre, when some 2,000 persons were present. The Rev. Dr. Lloyd, Provost of Trinity College, Dublin, the retiring president, was in the chair, and in the course of his address said that among the purposes of the Association was that "by a more rapid and extensive communication of the lights of science as they are struck out, and by carrying these things home to the doors of all, to awaken to exertion those gigantic powers of mind, which are not confined to a few favoured spots; but which are everywhere to be found; and by establishing a more immediate and intimate communication among those engaged in kindred pursuits, to unite their exertions, as it were, into one simultaneous effort, and thereby to accelerate the progress of discovery in every line in which the mysteries of nature may be penetrated by the ingenuity and perseverance of man".

At the conclusion of his address, Dr. Lloyd resigned the chair to the Marquis of Northampton, whose first action was to invite some of the ladies present who were without seats to occupy places on the stage, although they were "by law excluded from the platform reserved for the General Committee". His Lordship congratulated the meeting on the great accession of members the Association had received at Bristol. "Here," he said, "were men of every shade of denomination and opinion engaged in one united effort in the cause of science and truth—eminent men from foreign lands, united by the glorious brotherhood of mind, were here assembled to cement the intellectual union of nations. This he regarded as a political result of the highest and most gratifying order. The moral effect of the Association arose from truth being the great object of all its labours."

Death of Louis-Marie-Henri Navier

ON August 23, 1836, the eminent French engineer Louis-Marie-Henri Navier died in Paris at the age of fifty-one years. He was the son of a well-known lawyer of Dijon, where he was born on February 15, 1785. As a boy, owing to the death of his father, Navier came under the influence of his uncle Émilian-Marie Gauthey (1732–1806), an inspector-general of the Corps des Ponts et Chaussées. At the age of seventeen years, he entered the École Polytechnique and two years later the École des Ponts et Chaussées, the Government school for civil engineers founded in 1747 under the directorship of Perronet, and in 1804 directed by Prony. The mathematical training Navier received in these famous schools was reflected in all his later work. His first literary work was the publication of his uncle's "Traité de la Construction des Ponts", 1813. In 1819 he was made a professor of mechanics in the École des Ponts et Chaussées, and in the same year contributed to the Paris Academy of Sciences his "Mémoire sur la flexion des verges élastiques courbes", which was followed by his "Mémoire sur les lois de l'équilibre et du mouvement des corps solides élastiques", 1821, and his "Rapport et mémoire sur les ponts suspendus", 1824. In 1827 he investigated the general equations of equilibrium of an elastic solid, starting from an assumption as to the molecular constitution of matter.

While engaged in teaching and writing, Navier was responsible at the same time for the design of bridges, among which was a chain suspension bridge over the Seine at the Invalides in Paris, the bars for which he required to be tested to 11 tons per sq. in. Constructed in 1826, unfortunately one of the pylons failed, and the bridge had to be taken down. It was afterwards shown by Prony that the mishap was due to circumstances the designer could not have foreseen. The incident for a time had an unfavourable effect on Navier's reputation; but the esteem in which he was held was shown by his appointment in 1830 to the chair of analysis and mechanics at the École Polytechnique. Two years before his death he was given the rank of divisional inspector in the Corps des Ponts et Chaussées. His collected works were published after his death, and to the third edition of them Saint Venant added many valuable notes and corrections.

Christoph Wilhelm Hufeland (1762-1836)

Christoph Wilhelm Hufeland, physician, author, editor and philanthropist, the centenary of whose death falls on August 25, was born at Langensalza in Thuringia on August 12, 1762, the son and grandson of court physicians at Weimar. After studying medicine at Jena and Göttingen, he qualified in 1783, his inaugural thesis being on the value of electricity in asphyxia. For the next ten years he remained in practice at Weimar, where he was brought into close contact with Goethe, Schiller, Wieland and Herder, as well as with members of the court. In 1793, he was invited by the Duke of Weimar to accept a professorship at Jena, and his lectures attracted considerable attention. In 1880 he succeeded C. G. Selle as royal physician at Berlin, where he became director of the Medico-Chirurgical College and senior physician to the Charité Hospital.

Hufeland was an extremely prolific writer, more than four hundred articles being attributed to him, but his best known works are "Makrobiotik" (1805) or the art of prolonging life, which was translated into every European language and passed through eight editions, and "Encheiridion Medicum; or Manual of the Practice of Medicine", of which six editions were published, an English translation appearing in 1842. Of the four medical journals which he edited, the best known is the *Journal der practischen Arzneikunde und Wundarzneikunst*, which he founded in 1795 and edited until his death in 1836, after which it continued until 1844.

Hufeland was an enthusiastic supporter of Jenner, and did much by his influence to diffuse the practice of vaccination throughout Germany, in addition to founding a vaccine institute at Berlin. He took an active part in the sanitary reorganization of Berlin, recommended the general use of warm baths and deprecated the abuse of spirits. In 1810 he founded a medical polyclinic, the first of its kind in Germany, for the treatment of the indigent poor, and for the next twenty-four years published annual reports of its activities. Finally, he did much useful work in combating popular errors concerning the Brunonian system of philosophy, mesmerism and phrenology. He was generally regarded as one of the noblest characters of his age.

Sudden Deaths and Suicides in Russia

According to the *Gazette des Hôpitaux* of August 25, 1836, official reports show that during the course of 1832, 405 persons, of whom 324 were men and 81 women, died a sudden death in St. Petersburg. In 1833 the figures were considerably higher; 569 such deaths (353 in men and 216 in women) being registered. Most of these deaths were the result of intemperance. It is rare in St. Petersburg, the report continues, as in all the large towns in Russia, for public rejoicing not to cause the death of a large number of individuals. In 1833, for example, 78 men and 24 women were picked up in the streets of the capital whose deaths were due to drunkenness and cold. It is a well-known fact that in Russia, those who are so imprudent as to fall asleep in the open air after excessive consumption of strong drink never wake up again. In the course of the triennium 1831–33, 104 suicides were committed in St. Petersburg. It was noted that young persons made use of firearms or sharp instruments almost exclusively, while old people preferred drowning or hanging.

Societies and Academies

Dublin

Royal Dublin Society, June 23.

P. O'Connor: A contribution to knowledge of Irish fungi. A complete list of the fungi recorded by the author in Ireland during the past three years, with sites, dates and host plants and trees. A number of the species have not previously been observed in Ireland, and a few are new to the British Isles.

P. A. Murphy and J. B. Loughnane: A comparison of some Dutch and Irish potato mosaic viruses.

Phyllis Clinch, J. B. Loughnane and P. A. Murphy: A study of the aucuba or yellow mosaic of the potato.

H. H. Poole and W. R. G. Atkins: The standardization of photo-electric cells for the measurement of energy. The cells and colour filters used for the measurement of daylight have been standardized by means of a standard filament lamp so as to enable the radiant power per square centimetre in various parts of the spectrum to be found in absolute units. The relatively low temperature of the standard source and the relatively large effect of errors in its assumed colour temperature reduce the accuracy of the results.

J. Lyons: The influence of chemical composition on the firmness of butter. The exceptional firmness of New Zealand and Australian butters as compared with Danish and Irish butters is attributed to the relatively low unsaturated fatty acid content and high stearic acid content of the former.

J. A. C. Teegan: The comparison of γ-ray intensities from radium preparations. A valve method of measuring the ionization current allows the natural leak to be compensated, and is very rapid and convenient for routine measurements.

Paris

Academy of Sciences, July 6 (*C.R.*, 203, pp. 1–136).

International Economics and Social Reconstruction

THE narrow outlook which continues to characterize much of the controversy regarding sanctions, the refusal to face the implications of collective security, and the disposition to blame a mere organization such as the League of Nations for failures due to lack of courage and foresight on the part of statesmen in using the machinery ready to their hand, should dispel any optimism that we are beginning to grasp the essential principles upon which the future well-being of mankind must be constructed. We may well doubt that there is sufficient political sense and stability in Europe or Asia to make world recovery possible at all. To those who maintain that our whole civilization is slipping into disintegration and dissolution from which all our mastery of the material universe is impotent to preserve it, a satisfactory answer is not readily found.

Reasons such as these, and the way in which the continued difficulties experienced by our own and other Governments in handling international affairs betray lack of capacity for real leadership and foresight, may well lead to misgivings as to the future in spite of the undoubted fall in unemployment and increase in industrial employment and trade. How well-founded are such misgivings is indicated by the admirable survey of world economic and social conditions provided by Mr. Harold Butler, Director of the International Labour Office, in his Annual Report*. It is clear from this survey that no certain answer can yet be given to the question whether the past year should be regarded as marking the emergence of the world into the flowing tide of recovery or as merely an interlude of mitigated depression.

On the credit side of the economic balance sheet must be set a gradual improvement in prices and a continued decline in unemployment. In many countries, the general index of industrial production has moved steadily upwards; but in so far as this industrial prosperity is founded on the expansion of armaments, which notoriously is taking place in the principal industrial countries, it is hollow and unusual as well as sinister. The manufacture of arms adds nothing to national wealth, and the economic consequences of rearmament must be set in the scale against the apparent sign of economic revival. The universal alarm and anxiety which accompany intensive competition in armaments check the expansion of healthy trade and investment, and block the path of normal recovery.

The armament situation itself is thus reason enough for some misgivings about the present situation. The slight improvement in the volume of international trade, and the extent to which economic nationalism continues to hold the field, are other reasons for anxiety. Confidence in foreign investment is still lacking, and the major obstacle to the re-birth of confidence is the fear of war, imminent or not remote; and economic recovery is an impossible dream until this fear of another and more catastrophic collapse of the whole international political system has been dispelled.

Given a general will to seek that end in a constructive and co-operative spirit, the task is not yet impossible in spite of its increased difficulties; but it calls for the display of statesmanship of the highest order. It must be realized that the most radical flaw in the recent peace settlement was the failure to ensure economic and social equilibrium. Territorial claims and armament programmes are the symptoms—not the causes—of our present condition. The roots are to be found in actual or threatened impoverishment, declining standards of life, insecurity for the future of themselves and their children which darkens the outlook of the present generation in so many countries. The question of peace can no longer be discussed apart from that of social justice.

---

* Report of the Director, International Labour Office, Geneva, 1936.

On such grounds as these, Mr. Butler is led to a point of view which many scientific workers have reached, from their survey of the possibilities of the applications of science being utilized to raise the general standards of and amenities of human life, and to assist in the distribution of the economic resources now at our disposal. No longer can we think of life in terms of sub-divisions only. Artificial barriers which hamper our thought about men in society must be broken down and a synthesis of all the social sciences achieved which will permit a true notion of the structure and possibilities of society, just as it is only by a synthesis of all the sciences concerned with man and his environment that we can understand his nature.

Mr. Butler's brief summary of the immediate problems of social reconstruction which call for consideration has points in common, such as housing, with those which in Great Britain are already receiving the attention of such groups as P.E.P. (Political and Economic Planning), or nutrition, on which scientific workers have done much to provide a basis for action. Mr. Butler refers to the way in which these questions are linked to those of international trade and finance. The question of raw materials is similarly linked and is not even mainly a colonial problem. The countries which have real difficulties in procuring their supply of raw materials are those which have imposed restrictions in dealings in foreign exchange, due to their monetary or commercial policies. The problem cannot be divorced from the whole question of restrictions on commerce, including the question of the 'open door' in colonial territories which are large providers of certain raw materials.

These problems in themselves raise broad questions of colonial policy, not only in regard to raw materials but also in regard to labour and migration. The need for investigating such problems is now becoming generally admitted, and they can only be dealt with on practical lines if account is taken not only of general principles, such as are embodied in the Mandates Article of the Covenant of the League of Nations, but also of the conditions and requirements of each particular case. Not the least untoward consequence of Italian aggression in Abyssinia is the way in which it has enhanced the difficulties of an impartial and adequate treatment of questions which were already sufficiently thorny.

Last and most important of all in the programme of reconstruction is the problem of liberating commerce from the restrictions which have been imposed upon it by nationalist economic policies or on account of currency disorders. From whatever angle we approach the problem of reconstruction, the only path leading to its solution is that of closer international intercourse. The doctrines of nationalism and self-determination may within limits be beneficial and stimulating in the field of politics and culture, but in the field of economics they are fatal. Economic nationalism in its recently developing forms is incompatible with economic stability and therefore with the peace of the world.

The only way out of our troubles is, therefore, to restore so far as possible exchange of goods, services, money and population on which pre-War prosperity was founded, and which the rapid progress in means of communication has made all the more imperative. The new world economy to be built up, however, must take account of all the developments which have taken place since 1914. The great internal transformation in industry and agriculture cannot be set aside without causing still further confusion and upheaval. They necessitate a complete readjustment of method, but the ultimate objective is unchanged.

Mr. Butler gives us once more a survey which commends itself to the scientific worker alike for its presentation of the facts on a broad canvas free from the distortion of material or party bias as for its insistence on the necessity of viewing life as a whole. Economics cannot be separated from ethics, social justice from material well-being, or social and ethical aspirations from political activities. Peace itself is not possible without social justice between nations and between individuals, and only through an equitable organization of the world's economic life can peace and justice and freedom be made secure.

These views to-day are in danger of becoming platitudes, though they touch the quality and direction of scientific life and thought as of every other intellectual or physical activity. It is only as creative thought is brought patiently and impartially to bear on these questions that we can hope to find the lines of a solution; and the major question is whether sufficient moral and social pressure can be mobilized in support of constructive policies in which science plays its fitting part, before the reactionary forces of militarism and economic rivalry and autarchy bring the whole fabric of our civilization to collapse.

The root question behind this appeal for world co-operation is the choice between freedom and slavery of the spirit. Freedom of thought and speech, belief and investigation, subject only to the recognition of the same liberty on the part of others, is exactly what is threatened by the new tyrannies which, through their militarism and economic nationalism run mad, seek often in subtle ways to reduce the citizen to a soulless unit, to moral and intellectual servitude. The perpetuation of economic antagonism and military rivalries is as grave a danger to scientific thought and investigation, upon which so many of its material achievements are based, as it is to the continuance of our material civilization.

Manifolds of Plenary Space

Intrinsic Geometry of Ideal Space
By Dr. A. R. Forsyth. Vol. 1: pp. xxvi+553. Vol. 2: pp. xiv+655. (London: Macmillan and Co., Ltd., 1935.) 2 Vols. £6 6*s*. 0*d*. net.

IT is desirable to give the reader immediately an idea of what is an ideal space and its intrinsic geometry. Prof. Forsyth writes: "The present work is occupied with investigations of those intrinsic properties and differential measures of geometrical amplitudes which are connected with the corporate characteristics and the organic constituents of the amplitudes". Hence we see, if we do not know what is an ideal space, we know at least that we can substitute the word "amplitude" for it; and instead of "intrinsic" we can use "corporate" and "organic". That is all. We must seek an interpretation of these mysterious words going through the 1248 pages of this work. Before we can do that, we must become acquainted with some other words: plenary uncurved or homaloidal (Euclidean space); flat and block (Euclidean spaces of dimensions three and four); amplitude (manifold); regions and domains (manifolds of three and four dimensions); tilt and coil (third and fourth curvature); gremial, orbicular, and globular curvatures; and other curiously used words.

Passing over Eleusinian statements like this: "The homaloidal space is free from all native measures that can modify the geometrical character of included figures: its standardising influence is impartially neutral", we begin to examine the contents.

Section I, after an introduction where we discover the identity between homaloidal and Euclidean space (How can that be? Was it not free from any native measure?) and where we find the old Frenet equations, gives a sketch of Riemannian geometry (geodesics, Riemann's curvature), with a mixture of properties not belonging to this geometry but to the ordinary Euclidean geometry of the manifold (as embedded in a Euclidean space). Such are the researches on the locus of the centres of first curvatures of geodesics of a manifold V_n concurrent at a point: the cases when the dimensions of the plenary space (Euclidean space embedding the V_n) are $n+2$ or $n+3$ are discussed. In this second case two subcases arise; but no hint is given of the projective ground on which this distinction stands. Neither is there any suggestion of what may happen when that space has more than $n+3$ dimensions, although the number of possibilities is finite.

With Section II begin the limitations of the field of research; the author restricts his studies to surfaces (Section II), regions (Section III) and domains (Section IV) and to their subamplitudes. Here also we find properties of Riemannian character (geodesics, Riemannian curvature, Levi-Civita's parallelism, minimal surfaces and regions) scattered in different chapters, according to the dimensionality of the amplitude; also, when they are independent of it, mixed up with properties relating the amplitude to its Euclidean space. There is a wealth of particular results (new or not, that is difficult to state from quotations in the book), but no general idea. It is a kind of empirical 'going on', step after step, with apparently no goal to be reached. The method of attack has also the same empirical character: it would certainly be inadequate for a research of broader frame.

Now some selected topics. Section I contains some theorems which can be summarized as follows: the second, third and fourth normal of a geodesic of an amplitude (at a point) lie in the tangent homaloid of the amplitude. This is a serious mistake, and no calculations are necessary to check it. In fact, not only is the reasoning on which it is established evidently wrong, but, should it be true, it would lead to the amusing conclusion that the geodesics of any surface whatever belong to spaces of three dimensions! This mistake is of no little moment: it invalidates many results in different sections of the book.

Section II opens with the following question: Is it possible to find a lower limit to the dimensionality of the Euclidean space (plenary homaloid) containing a surface with a given arc-element? The answer, given by Darboux in 1872, and referred to in all standard treatises on the subject (like Darboux's and Bianchi's) is in the affirmative. It is always possible to construct such a surface in a space of three dimensions by integrating a Monge-Ampère equation and by quadratures. Prof. Forsyth's answer is in the negative*: it is true that he speaks of an upper limit, but what he means (as can be seen from the discussion) is a lower limit. This is all the more reason that a search for an upper limit has no value, it being evident that, given a surface in a 3-space, surfaces with the same arc-element can be found in a space with greater number of dimensions. Prof. Forsyth seems struck by the example he gives of a surface in a space with an infinite number of dimensions: there is nothing surprising in it, the dimensionality of the space having nothing to do with the arc-element of the surface (it is not a Riemannian character).

Another topic to be mentioned—and this will be the last one—is the statement, often repeated and invalidating many results, that when a certain determinant vanishes (see, for example, vol. 1, p. 369) or, what is the same thing, when the first and second derivatives of the co-ordinates of a point of a surface are not linearly independent, the surface lies in a quadruple homaloid. To make the mistake more curious, the example given before of a surface belonging to a space with infinite dimensions contradicts the last statement. But this is only one example, and the simplest one, of the contradictions which arise when the projective characters of the manifold are not considered. I have emphasized many times the fact that, when studying the differential properties of a given order (of differentiation), the basic element to be considered is not the dimensionality of the space in which the manifold is immersed (which may also be infinite, with no danger) but the dimensionality of certain osculating spaces (as I call them) projectively connected with the manifold.

The author describes his book as an adventure into the realm of investigating manifolds (not curves or hypersurfaces) existing in a plenary space. Thirty years ago, E. E. Levi (who is not quoted in this work) entered the same realm, harvesting the first results (for two-dimensional surfaces) and showing its difficulties. More than twenty years ago, I tackled the problem again, and conceived the idea of Riemannian geometries of higher species ("Geometrie Riemanniane di specie superiore". *Mem. R. Accad. d'Italia*, 1935), showing that the differential properties of a given order r of a manifold (whatever its embedding space may be) can be described in terms of r differential forms of the first order and of $2, 4, \ldots, 2r$ degree. But the step was not easy. To fill the gap it was necessary to build up the projective differential geometry of manifolds, or more exactly of linear partial differential equations. In the meantime, other investigators have taken part in the work, as Vitali, Enea Bortolotti, Burstin, Duschek and Meyer; apparently passing over all this work, Prof. Forsyth has followed his own way.

E. Bompiani.

---

* The correct result is given in a corrigenda sheet which has been issued since publication of the book.

Sea Urchins

A Monograph of the Echinoidea
2: Bothriocidaroida, Melonechinoida, Lepidocentroida and Stirodonta. By Th. Mortensen. Text. Pp. vi+647. Atlas. Pp. ii+16+89 plates. (Copenhagen: C. A. Reitzel; London: Oxford University Press, 1935.) 2 vols., 140s. net.

THIS monograph attracts a review, for it exhibits features of a distinctly novel nature and it approaches perfection as near as can be. The animals are the box-like sea-urchins, starfishes with radiating segments and brick-like walls (tests) decorated with spines and fine sculpturing. They walk by outpushings of fine tubes (tube-feet) with terminal sucking-disks arranged in five rays, such as cause starfish to be of unique personality. They belong to Mortensen more than to anyone else, for he has pursued the living forms in most parts of the world. Here, his study of the urchins' habits, food and ecology was antecedent to that of their classification, and he thus by analogy can tell us much of the life of the extinct forms. Of the latter there is a long series from the Palæozoic, and it would seem probable that these animals have never been less numerous either in genera and species or in individuals than they are to-day. Thus the relatively deep-living Salenidæ had eighty-five species in the Cretaceous as compared with only twelve species to-day, but all the extinct forms were not deep-living.

The first animal here considered, *Bothriocidaris*, was formerly regarded as the ancestor of all sea-urchins, but more ancient forms are now known, and Mortensen evidently places it here to avoid making another phylum. He supposes that it must have ingested food through the mouth, probably the adoral spines and tube-feet helping as in the living spatangoids. Judging by the deposits where it occurs, it lived in shallow reef-pools, which, according to the indications furnished by its test, cannot have been exposed to strong wave-action. It is this thought of the fossil forms as once alive and playing their parts on the ocean floor which makes this monograph so illuminating, its animals far more than mere dates in a stratigraphical series and its living forms the few survivors of a long ancestry.

Only three divisions (Melonechinoida, Lepidocentroida and Stirodonta), besides Bothriocidaroida with its single genus, are monographed. They contain 22 recent and 116 fossil genera. All the genera are described, while in addition the 84 existing species are fully considered in respect to their anatomy, colour, occurrence and, so far as possible, their ecology; the text illustrations of the anatomy form a feature of great utility. The same technique is applied to the fossil genera, the anatomy of which is illustrated while their affinities are considered. Many of the species are referred to, but it is beyond the author's scope to consider all the described fossil forms. Added to the monograph is a volume of plates of high quality.

The whole is of great credit not only to Mortensen but also to Denmark and to the managers of the Carlsberg Fund, whose financial aid alone made possible the printing of this luxurious publication, which it is a joy to handle. J. S. G.

Negroes and Pygmies

My Pygmy and Negro Hosts

By Paul Schebesta. Translated from the German by Gerald Griffin. Pp. 287+31 plates. (London: Hutchinson and Co. (Publishers), Ltd., 1936.) 18*s*. net.

FATHER PAUL SCHEBESTA, whose intimate knowledge of the pygmy problem, acquired in the Far East as well as in Africa, transcends that of any living ethnologist, has now produced a sequel to "Among Congo Pigmies". In this he supplements his earlier work on the Congo pygmies by an account of the Batwa of Ruanda and the Bachwa of the Equatorial Province, who, if not all pygmies, at least merit the title of half-pygmies. More important, however, for his present purpose, are the tribes of full stature with whom he came into contact on his travels in 1929 and the two succeeding years.

Interesting for the ethnologist as must be the comparison of the material relating to the pygmy peoples given here with that of the previous book, it will probably appear to most readers that the author has displayed sound judgment in devoting the larger share of his attention to the tribes other than pygmy. For one thing, this material is essential for an understanding of the ethnological background, in view of the close relation, almost a symbiosis, between the pygmy and his taller neighbour, while in the second place, the culture of these peoples is both intrinsically interesting, and for the most part has not previously been described. Witchcraft, cannibalism and tribal history afford the author a rich field for description. It may be hoped that material for a fuller and more systematic analysis of the last named will be forthcoming later. Some further details, too, of the evidence upon which is based the suggestion of a surviving influence from Ancient Egypt will be welcomed.

The author was much impressed by his visit to the Royal Court of the intrusive Batutsi of the mandated territory of Ruanda, in which, as he points out, there are certain close resemblances to the court of Uganda. He was admitted to the presence of the Royal Mother—a privilege formerly denied to the foreigner, and evidently resented. Shortly after, the dynasty was deposed by the Belgian authorities.

The narrative offers innumerable tempting paths which would lead to discussion, such as, for example, the association of initiation ceremonial with a cannibalistic 'leopard' society among the Babali, where also initiation takes the place of circumcision, universal among the other tribes. The author himself was responsible for the discovery of a secret 'leopard men' society and its association with cannibalism among the Babali.

At the present moment, when African colonies and mandated territories are much under discussion, Father Schebesta's final chapter, in which he deals with the relations of black and white in the Congo, will be found to contain much that is pertinent. Belgium, he points out, is intensely proud of the possession of the Congo and has made immense sacrifices for its benefit. Since the Great War, a complete change has taken place in the spirit of the administration, and every effort has been directed towards the benefit of the natives. In the main these efforts have taken two directions —the building of roads and the formation of an administrative organization for the government of the natives in accordance with their own cultural ideas. As the author points out, the making of roads has conferred no benefit on the natives, while imposing on them a heavy burden of upkeep; and the system of headmen or *chefs de section* has been applied without discrimination. In certain instances it was applied to peoples to whom it was not adapted; in others the headman, as happened also at times in British mandated territory, was merely a figure-head, because the real native rulers, the spiritual chiefs, remained in the background and continued to receive the peoples' allegiance Apart from the author's criticisms, there is evidence here and there in his narrative that the administrative system lacks the necessary basis of a scientific study of native institutions, which has been recognized elsewhere as a necessary preliminary, however superficial it may have been in practice, owing to lack of time or other impeding conditions.

New Ornamental Trees and Shrubs

Trees and Shrubs hardy in the British Isles
By W. J. Bean. Vol. 3. Pp. xiv+517+64 plates. (London: John Murray, 1933.) 36*s*. net.

DURING the planting season, those of us who wish to make our gardens more attractive by the addition of flowering shrubs or trees, scanned nurserymen's catalogues for some of the more showy and less commonly seen species, so many of which have been introduced in recent years. The wanderings of Forrest, Kingdon Ward, Wilson, Farrer, Comber and Rock have greatly increased the possibilities for variety. Now that the new introductions have been tested as to adaptability to our climate, at Kew, Edinburgh, Wisley and elsewhere, seeds and plants of those which have proved satisfactory are becoming available for distribution, at a moderate price, to gardens with only limited space.

Those who are looking for new and interesting species would be well advised to study carefully the third volume of Bean's "Trees and Shrubs hardy in the British Isles". This is a supplementary volume to the first two, which were issued in 1914; it has been written with the same care and precision, and that unrivalled personal knowledge of the plants themselves and their requirements, which are so characteristic of all Mr. Bean's work. It comprises 517 pages and includes 64 full-page illustrations from photographs by such well-known lovers of trees as Lieut.-Colonel Stephenson-Clarke, Dr. Wilfred Fox and the late Dr. E. H. Wilson, and others by R. A. Malby and Co. These, in themselves, are a joy to look at; where all are beautiful and well-selected, it is almost invidious to mention any in particular, but perhaps *Magnolia sinensis; Pyrus* (*Sorbus*) *munda* var. *subarachnoidea* with its white fruits showing beautifully against a dark background; *Halesia monticola* with its bell-shaped flowers; and the charming habit photograph of *Cercidiphyllum japonicum* at Westonbirt, are worth especial mention.

Magnolia sinensis Stapf, from West Szechuen, China, where it occurs at 7,500–9,000 ft. altitude, is said to be perfectly hardy, forming a pleasant addition to the list of magnolias. It is described as a deciduous shrub or small tree, bearing saucer-shaped, fragrant white flowers 3–4 inches across, having rosy-crimson stamens; a useful feature is said to be its ability to thrive in a chalky soil. *Meliosma beaniana* Rehder and Wilson, from Hupeh and Szechuen, is said to grow "healthily" at Kew. Wilson described it as one of the most striking and handsome of Chinese trees, with leaves 6–12 inches long, and creamy-white panicles up to 8 inches long and 4 inches wide.

Of *Cornus kousa* var. *chinensis* Osborn, Mr. Bean says that this beautiful flowering tree should be in every garden, being perfectly hardy and blossoming at a season when most hardy trees and shrubs are out of flower. It is encouraging to read of a *Paulownia* (*P. fargesii* Franchet) which seems to be hardier at Kew than is *P. imperialis*.

Ceanothus cyaneus Eastwood, is described by Miss Eastwood, the veteran curator of the California Academy of Sciences herbarium, in Golden

Gate Park, San Francisco, as "certainly the loveliest of all the species of Ceanothus, with its large sprays" of flowers of a lovely bright blue, each about $\frac{1}{4}$ in. across. It is grown at Kew on a wall facing east, but suffered from frost in the spring of 1932, and Mr. Bean thinks it will probably be seen at its best nearer the south coast.

Of other genera represented in gardens by well-known species, many novelties are described, including 29 of *Berberis*, of which 3 are figured; *Betula* 7; *Buddleia* 11, *Ceanothus* 7, *Pyrus* 26, *Prunus* 16 and *Pittosporum* 11.

Of the New Zealand genus *Olearia* (daisy bush), of which the hardy *O. haastii* is the best known, twenty-four species are described, most of which, unfortunately, are hardy only in the mildest parts of Britain.

The genus *Rhododendron* comes in, of course, for the greatest attention, the account of it occupying 91 pages (out of the total 517), 173 species or hybrids being described and 14 figured.

The value of the book is indicated by the fact that a second edition has just been published.

Mathematics and Agriculture

Mathematical Treatment of the Results of Agricultural and other Experiments
By Prof. Dr. M. J. Van Uven. Pp. vi+310. (Groningen and Batavia: P. Noordhoff, N.V., 1935.) 9.50 f.

WE have become accustomed in Great Britain, mainly through the writings of Prof. R. A. Fisher, to the idea that accurate field experimentation in agriculture and cognate sciences is only possible through bringing certain principles of experimental design, mainly mathematical in character, to bear on the problem before the experiment is carried out, and then building up an arithmetical technique, based on the theory of statistics, for the working out of the data resulting from the experiment.

Dr. M. J. Van Uven, who is professor of mathematics in the Agricultural University of Wageningen, Holland, has been associated for many years with agricultural experimentation, and in this book he is concerned to place before readers a careful exposition of the mathematical and technical methods which are needed. He is not writing for the worker who merely desires a formula for the working out of a mean or a standard error. On the other hand, he wishes to be understood by a reader with only a modest equipment of mathematical knowledge. The result is a book, the first half of which is a carefully written and particularly full treatise on least squares. No appeal is made to other than straightforward algebra, but even so the book is by no means easy reading. The general subject is the adjustment of observations, direct and indirect, in one or more variables, including the choice of the representative value, the calculation of mean error of single observations, and of functions of these, and an elementary exposition of probability.

In the second part the author takes up the study of field experiments, beginning by showing how yields of plots can be adjusted when there is a regular fertility distribution. When this condition is not satisfied, he shows how to separate out the systematic and accidental causes of variation by means of an analysis of the variance of the yields. He considers the case of two treatments on alternate plots, and describes his method of working out the standard error of the difference between the treatment means. He recognizes, however, that such an arrangement is far from ideal, and proposes instead that the original plots should be divided to accommodate the number of treatments it is desired to test. This makes the trial one of a larger number of plots of smaller dimensions, but the author does not say how the treatments should be arranged within the plot, whether at random or systematically.

A long description follows of Fisher's methods of block trials, including as a special case the Latin square. There is much to interest the reader here in the exposition of the algebra of the method, and its various ramifications, but the author does not point out that one of the essential features of the methods is the random arrangement. Indeed his examples are systematically arranged, although he does point out, in the case of the Latin square, that some re-arrangement would be advisable to prevent the same treatment occurring down the diagonal.

The author returns to least squares in the last chapter, dealing with the adjustment of direct conditioned observations, and four appendixes are added dealing in detail with points arising in the text. The last, indeed, gives the complete technique of solution for normal equations.

The book is well and attractively printed, and there are few misprints. J. WISHART.

The Atom

By Prof. E. N. da C. Andrade. New edition, entirely revised, extended and reset. Pp. ix+129. (London and Edinburgh: Thomas Nelson and Sons, Ltd., 1936.) 1*s*. 6*d*. net.

PROF. ANDRADE dedicates this little book to two friends as a memorial to "a lively, learned, and humane luncheon table", and thereby sets the tone of what follows. Starting with an account of the meaning of the atomic theory, he takes the reader smoothly along, with many a well-chosen analogy and an occasional jest, dealing with the atom of electricity, the nature of light, the structure of the atom, the mechanism of radiation and, in the concluding chapter, with the relation between matter and energy.

We read of the positron, neutron, wave mechanics, quantum theory of spectra, transmutation of atoms and artificial radioactivity, all in a descriptive narrative using everyday illustrations to make difficult conceptions clear. A large ship, with engines stopped, rolling and pitching on the open sea, reveals by its motion to an observer in an aeroplane that the sea is rough even though he cannot see the waves; so the Brownian movement in a liquid reveals the motion of its molecules. Cigarettes of various sizes are sold, but we have to buy a whole number; similarly, the quantum of radiant energy varies with frequency, but we never find less than one quantum, whatever the frequency. A given kind of atom may be regarded as singing two characteristic songs in the bass (flame and spark spectra) and one in the high soprano (X-ray spectrum).

Prof. Andrade's hope that he will arouse a desire to pursue the subject further will surely be fulfilled. We may commend the book also to senior physics pupils in schools, who will obtain from it a broad and often novel view of recent developments in their subject.

The Identification of Trees and Shrubs:

how to name without previous Knowledge of Botany any Wild or Garden Tree or Shrub likely to be met with in the British Isles. By F. K. Makins. Pp. vii+326. (London: J. M. Dent and Sons, Ltd., 1936.) 15*s*. net.

THE appearance of a book that aims at supplying the means of identification of trees and shrubs that occur in Britain—wild or cultivated out of doors—should meet with a wide appeal. It is true that the indigenous woody species, which number only a few dozen, may be readily named from existing floras and handbooks, and that there are excellent works describing the legion of trees and shrubs now in cultivation; nevertheless, so far, there has been no attempt to provide a general key or other ready means of identification of the cultivated species, and the present work is a pioneer in this respect.

The book is easy of reference and assumes no previous botanical knowledge. Only those species that the author considers most likely to be met with are considered, rare or little-known plants being purposely omitted. In spite of this limitation, the number of woody plants dealt with is 1,732, or rather more than half those listed in the Kew "Handlist of Trees and Shrubs" (1934) which places the total number at about 3,000. Each species is represented by a small illustration or diagram, and is briefly described in the later part of the volume. A preliminary key on basic leaf characters serves to direct the user to the requisite group of diagrams to which any particular plant may belong.

The work should prove useful, particularly in naming the more generally cultivated trees and shrubs; but limitations of size must effect its usefulness in the case of the larger genera with numerous closely allied species, for example, *Rhododendron*, *Cotoneaster*, *Crataegus* and certain *Coniferae*.

Insect Pests of Glasshouse Crops

By Dr. Herbert W. Miles and Mary Miles. Edited by H. C. Long. Pp. 174+21 plates. (Surbiton: H. C. Long, The Birkins, Orchard Road, Hook, 1935.) 8*s*. 6*d*. net.

GLASS-HOUSE cultivation provides a type of environment which favours the spread and multiplication of a variety of insects and related creatures of injurious propensities. At the same time, these conditions afford facilities for pest control that are often exceptional. The growing extension of the glass-house industry has brought the cultivator up against the problem of pest elimination more realistically than in years gone by. New pests have come to light, species formerly regarded as innocuous have, after proper study, proved to be the reverse, and the list of known invaders has assumed considerable proportions.

Much valuable information is now available on the subject of glass-house pests, but it has mostly remained inaccessible to the amateur and to many professional growers. Dr. and Mrs. Miles have thus supplied a much-needed requirement in the book under notice. Their experience and qualifications have well fitted them for their task and they have produced a sound, up-to-date manual covering the whole range of pests likely to be met with. These are clearly described, along with their life-histories, and the most practical and efficacious methods of control. The book is well illustrated with a remarkably good series of clear photographs, almost all being hitherto unpublished. It can be recommended to all interested as one which is based upon practical experience and not merely compiled from the writings of others.

A. D. I.

Odyssey of the Islands

By Carl N. Taylor. Pp. xiv+284+31 plates. (New York and London: Charles Scribner's Sons, 1936.) 12*s*. 6*d*.

MR. TAYLOR describes himself as a 'vagabond', and entertaining as this record of a vagabond's wanderings may be, it does not call for extended notice here. It is, however, to be noted as giving a view of life among the wilder peoples of the Philippines, which includes an account of the too little known and often unapproachable pygmies. The book is illustrated by some excellent photographs.

The Total Solar Eclipse of June 19, 1936

Observations at Omsk

By Prof. J. A. Carroll, University of Aberdeen

THE expedition of the Joint Permanent Eclipse Committee of the Royal and Royal Astronomical Societies, and the University of Aberdeen, which was stationed at Omsk, had the good fortune to observe the total solar eclipse of June 19, 1936, under excellent conditions.

The expedition consisted of five members, namely, Prof. J. A. Carroll, professor of natural philosophy in the University of Aberdeen (leader); Mr. E. G. Williams, Solar Physics Observatory, Cambridge; Miss F. M. MacBain, Natural Philosophy Department, Aberdeen; and two volunteer observers, Mr. W. M. Alexander, Aberdeen; and Capt. S. I. Luck, London.

Our programme contained only three principal items, but as the instruments, methods and auxiliary equipment were in many respects quite novel, some detail of description will be of interest to readers of NATURE.

To deal first with the observing instruments themselves, and the results yielded by them:

(1) A very rapid objective prism spectrograph specially intended for exploratory work in the infra-red region of the coronal spectrum, but, of course, also used on the flash spectrum. Five 60° prisms were followed by an objective of two inches aperture and twenty inches focal length, giving a dispersion of about 100 A. per mm. at 9000 A., and covering the range from the *D*-lines of sodium to about 11,000 A. on several pieces of plate of different types. The plates used were (1) Ilford S.R. Panchromatic, (2) Agfa 800 Contrasty, (3) Agfa 950.

We were particularly concerned to detect the coronal radiation at about 9600 A. predicted by Rosenthal[1] on the supposition that the major coronal lines are due to excited helium atoms, and also to observe the line at 7896 A. observed by Curtis and Burns[2] in 1925 and recently observed by Lyot[3] at the Pic du Midi without eclipse.

Plates sensitive so far in the infra-red have in general poor keeping qualities, and the plates used were sent by air and by special messenger from Berlin as shortly before the eclipse as possible. We are much indebted to Messrs. Agfa for the prompt supply of fresh plates and to the British Embassy in Moscow and the Poulkovo Observatory for their rapid transit to Omsk, where we could keep them on ice. Thus our plates were in good condition, and thanks to the thermostatic control the instrument performed well.

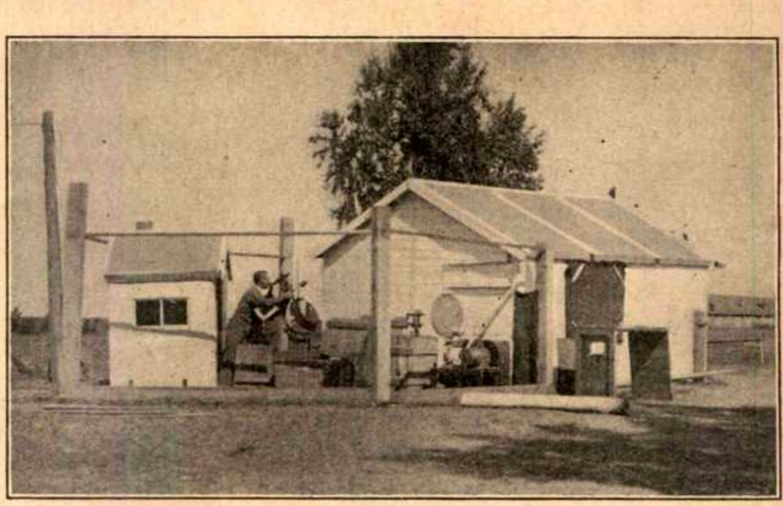

FIG. 1. Exterior of the cœlostat and experimental hut, looking east. The double-walled hut on wheels for sheltering the cœlostat is on the left. The larger hut is the double-walled, felt-lined hut for thermostatic sheltering of the instruments. At the nearest corner of the large hut can be seen the compressor for the refrigerator plant, and just above it the circular window to admit the horizontal beam from the cœlostat.

The plates show many flash lines and a number of coronal rings. Four exposures were given, (1) 5 sec. on the first flash, (2) 20 sec. on the corona, (3) 90 sec. on the corona, (4) 7 sec. on the second flash. Timing was good, and both flashes are satisfactory. In the flash spectrum, the Ca II triplet at 8500 A. is strong, the usual features show in the visible region and there are several strong lines in the region 9000 A.–10,000 A. not yet certainly identified, probably including a line due to helium. On the coronal exposures 6374 A. is strong and also the line near 7890 A. There is no strong radiation in the expected region near 9600 A., though later examination may reveal traces. The plates were good enough to show strong lines down to 10,000 A. It is interesting to note that at mid-totality prominences show, in $H\alpha$ and the *D*-lines, on both sides of the solar disk.

(2) An objective interferometer of 13 cm. aperture and 105 cm. focal length for the study

of the corona in its own monochromatic green radiation at 5303 A. The aim of this instrument is not, as some seem to have thought, to obtain accurate wave-lengths of the coronal green line. As this line is about 1 A. wide, the use of an interferometer for such a purpose is futile. The point is that by introducing a Fabry-Perot étalon into the optical train of a suitable objective spectrograph, one obtains a spectrograph working in all directions simultaneously as it were, and can obtain at all points of the corona the sort of information given by a powerful prism instrument, with a slit, over a small region only. Thus the variation in wave-length, strength, profile, and width of the line selected may be observed, and rotation and internal motion of the coronal material measured.

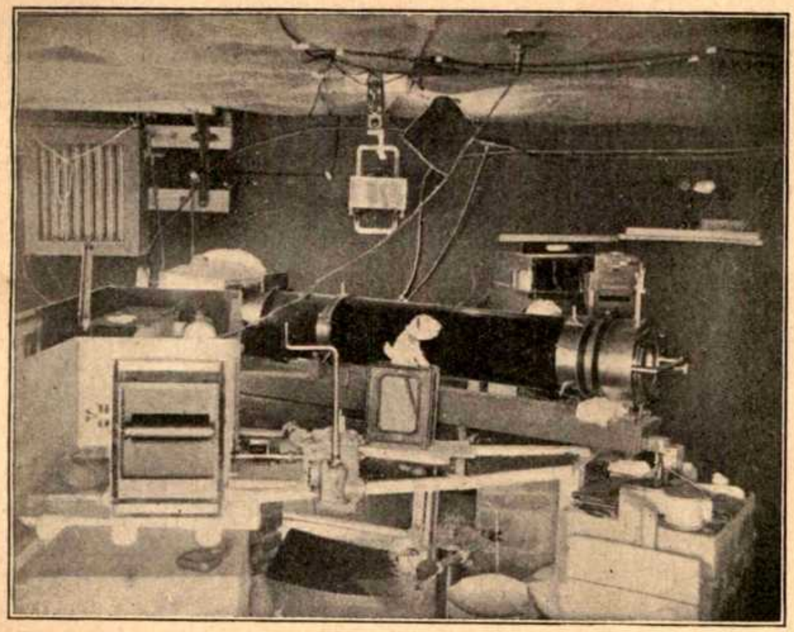

FIG. 2. Interior of experimental hut, showing echelon spectrograph, interferometer and infra-red objective prism spectrograph, with roof and sides of inner thermostatic chamber removed. One of the cooling coils of the refrigerator plant can be seen just above and to the left of the window admitting light from the cœlostat. In the opposite corner is one of the fans of the heating elements. In the centre of the ceiling are two thermostats controlling the cooling and heating elements for hut temperature. In the foreground is the heater element (surmounted by the Expedition's mascot) for fine control of instrument temperatures.

Two 6-inch 45° prisms dispersed the continuous spectrum sufficiently to allow the green ring to show by contrast, and the Ilford Astra VI plates were used, as these have a narrow maximum of sensitivity at 5300 A. with good resolving power and contrast. The plates of the étalon were separated by 1 mm. and were coated with aluminium *in vacuo* in an apparatus specially constructed in the Natural Philosophy Department at Aberdeen, so that the coating was uniform to a fraction of one per cent and the density could be exactly controlled. Thus the greatest resolving power obtainable for the loss of light allowance was secured.

The objective was a triplet of 6-inches aperture specially computed and made by Messrs. Adam Hilger, Ltd. The instrument worked excellently, and comparison fringes obtained during eclipse show exquisite definition at the full aperture.

Most unhappily, the light from the sun was cut off from this instrument during the total phase by a trivial accident, and only the comparison fringes remain to show the excellence of its performance. These are, however, not without interest in view of the remarks later on the need for, and benefits of, thermostatic control of eclipse instruments.

(3) An echelon spectrograph with automatic camera giving successive exposures of about 1·5 seconds for the study of the flash spectrum. It is of great interest to obtain accurate measures of the shapes of the chromospheric emission lines and of the changes in their shapes with height in the chromosphere. As these lines are only some 0·5 A. or so in width, very high resolution and dispersion are needed. An echelon spectroscope, crossed by, say, a pair of prisms, is almost the only instrument satisfying the necessary conditions for this type of observation, but so delicate an instrument is hard to use under eclipse conditions, and further, no echelons of large aperture exist.

The Natural Philosophy Department at Aberdeen possesses a very fine transmission echelon of 33 plates, each 1 cm. thick, height of step 1·1 mm., width 37 mm. This is still a very small aperture, but in view of the great interest of the observations and the great expense of a larger echelon, it was decided to attempt the observation of the flash spectrum with this instrument despite its small aperture. The information obtained would in any event be of vital importance in showing the practicability of the method and the size of instrument needed for accurate measurements, even if the flash spectrum turned out to be under-exposed.

As ordinarily used in air, the instrument had too small a separation between successive orders for use on the chromospheric lines, and the expedient of using the echelon immersed in oil of suitable refractive index was tried. Fortunately, the plates of the echelon turned out to be sufficiently homogeneous to permit this, and the main difficulty was due to the now abnormal sensitivity of the instrument to temperature changes. Liquids all have a temperature coefficient of refractive index some ten or more times that of glass, and to maintain homogeneity to a small fraction of a wave-length in a column of liquid 40 cm. long by some 8 cm. square proved a formidable task. Success was ultimately attained by careful thermostatic control, combined with the use of concentric thick-walled chambers of good conducting material (brass or copper) separated by air spaces or lagging, so that the echelon and its oil were surrounded by three such 'tunnels', and uniformity of temperature was satisfactorily obtained. The optical and mechanical details of the instrument are far too elaborate to describe in a short article. In essence, the appropriate portion of the chromospheric arc is picked out by a specially designed image rotator and achromatic collimator, and the light dispersed horizontally by two flint prisms and vertically by the echelon. The resulting spectrum is received on a film in a camera automatically operated to expose for about 1·5 sec., then move the film forward in about 0·2 sec. and expose again as often as desired.

The spectra obtained at eclipse proved too faint for useful measurement of flash lines, but the spectrum of the disappearing limb of the sun is well exposed for a study of darkening towards the limb in the last minute of arc over the region 4000–5000 A. It is of interest to note that the Fraunhofer lines seem to have almost completely disappeared by 10 seconds before second contact. The results given by this instrument suggest several possible avenues for exploration at future eclipses, and give accurate data enabling the design of a larger instrument to be undertaken with confidence in its adequacy and practicability.

Perhaps the most interesting and striking feature of our programme was the temperature control of the apparatus.

Modern eclipse observing requires the utmost of the optical performance of the instruments, and it is quite idle to set up spectrographs of any size with prisms and lenses, etc., figured to the last fraction of a wave-length, and expect any but mediocre results if they are subject to the ambient diurnal temperature changes. Still more is this so if interferometric apparatus is used. In Omsk the diurnal range of temperature was some 11° C., and this fluctuation was about a mean temperature that varied every few days from about 10° C. to 25° C. Ordinary lagging and screening by temporary shelters is hopelessly inadequate to deal with this, and it was decided to attempt complete and accurate temperature control as practised in the laboratory.

For this purpose the cœlostat mirror was of pyrex glass, and instead of the usual temporary canvas shelter a well-ventilated double-walled wooden hut, on wheels, was used to prevent undue fluctuation of mirror temperature. The performance of the mirror showed these precautions to be adequate so far as the cœlostat mirror is concerned, though a fused quartz mirror would be worth while. As the cœlostat must necessarily be uncovered in use, more accurate thermostatic control of it is impracticable.

The spectrographs themselves were very elaborately housed and controlled. Steady thermal conditions were obtained in two stages. First of all, a coarse control of the interior of the experimental hut. This hut was of wood, double-walled and felt-lined, with canvas screens (kindly supplied by the Willesden Paper & Canvas Works, Ltd.) for roof and walls. The mean temperature inside was maintained at about 15° ± 1° C. by means of a 1½ h.p. compressor and refrigerating coils (air conditioning units) lent by International Refrigerators, Ltd., and also by two 1 kw. low-temperature heating frames interlocked with the refrigeration control and regulated by a thermionic relay. Within the hut the instruments themselves, supported on masonry piers, were further enclosed in a lagged wooden chamber maintained at 1° C. ± 0·01 above mean hut temperature by thermostat and thermionic relay operating a low-temperature heater only. Tests of heat transfer in Aberdeen showed this system to be practicable and able to deal with the variation of external conditions expected in Omsk.

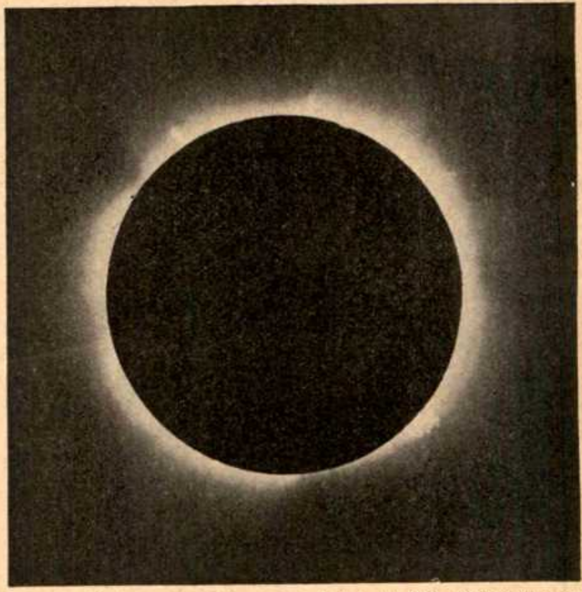

FIG. 3. Photograph of the corona taken by Mrs. Balanovsky, of Poulkovo Observatory, at Omsk. Lens, 5 m. focus; 10 cm. aperture; exposure, 1 sec. on Ilford Special Lantern Plate. By courtesy of Prof. B. P. Gerasimovic, director of Poulkovo Observatory.

It is very gratifying to be able to report that the installation, despite its elaboration, worked excellently. Some sixteen separately wired and fused circuits drawing currents of from ½ ampere to 20 amperes were needed and were required to operate smoothly for a fortnight or more before the eclipse ! Some troubles avoidable on a future occasion were experienced, but nothing disastrous, and the vagaries of electrical supply usual in remote districts were nobly reduced by the Omsk Electrical Supply Authorities despite our being some 8 km. from the generating station, on a line supplying heavy loads *en route*. Without the willing co-operation and special provisions of the supply authorities our efforts would have been nullified, and the way in which this unusual demand was met was typical of the treatment our Expedition received in the U.S.S.R.

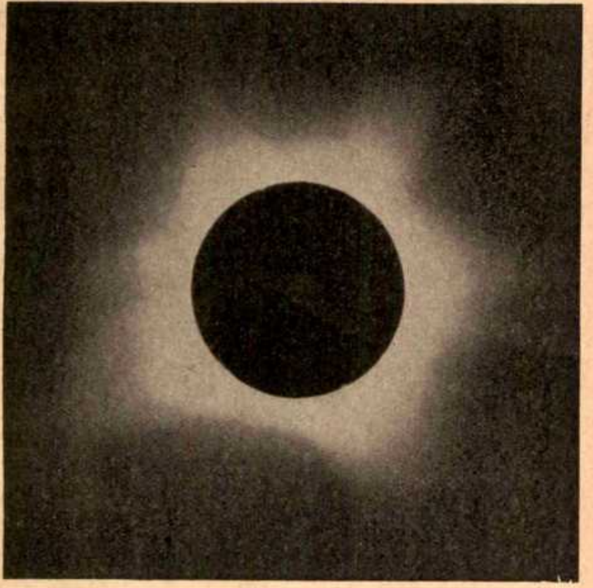

FIG. 4. Photograph of the corona in ultra-violet light taken by Dr. G. Tikoff, of Poulkovo Observatory, at Sara. Lens, 1·5 m. focus; 8 cm. aperture; exposure, 36 sec. on Ilford Special Rapid Plate. By courtesy of Prof. B. P. Gerasimovic, director of Poulkovo Observatory.

It would have been idle to take such elaborate precautions to ensure perfection of optical performance if the photographic materials had not been equally carefully prepared, tested and selected. The resolving power of many suitable emulsions, as well as their sensitivity, was carefully measured in Aberdeen, and the equipment so designed that the optical resolution attainable could be fully utilized. We are much indebted to the Research Department of Messrs. Ilford, Ltd., for the willing preparation of special materials and samples for this work and to Mr. Olaf Bloch for much time spent in valuable discussion.

One point of anxiety that was difficult to relieve by tests made in advance was the question of the correct temperature of stabilization for the instruments. Any desired temperature could be maintained, but clearly the desideratum is to have the instruments as near as possible to the actual temperature of the outside air at mid-totality. The expected temperature, based on mean diurnal records and calculations of temperature drop during the partial phase, was 15·5° C. The eclipse day itself was cooler than average, and the actual temperature was only 13·5° C. at mid-totality. The light was admitted to the instruments through a hole in one end of the hut, and a corresponding hole in the interior casing. These apertures were fully opened some five minutes before second contact and all temperature controls disconnected, the aperture into the hut being opened and the coarse controls suspended some 15 minutes earlier. The definition during totality proved excellent and the trouble feared from air currents did not arise.

The general 'seeing' was very good, and as the down-coming beam from the sun had to pass over the roof of the hut, this was covered for the greater part of the partial phase by a Willesden canvas sheet, removed shortly before totality and leaving the roof itself in good temperature equality with the surrounding air.

It is with great pleasure and gratitude that we can say in conclusion that no praise is too high for the arrangements made for us and facilities given for ourselves and our apparatus. On all sides we met with cordial co-operation, and a willingness to cut through routine procedure to expedite or to simplify our task. The special committee appointed by the All Union Academy of Sciences made excellent arrangements, which were well carried out, and the Government of the U.S.S.R. granted us exceptionally favourable rates for transport and housing, so that it was possible to take out sufficient equipment and personnel to execute this elaborate programme in the middle of Siberia. To Dr. B. P. Gerasimovic, director of Poulkovo Observatory, in particular, we are especially indebted for his personal attention to the hundred and one points of detail, as well as for the major planning of the arrangements made for us in the U.S.S.R. By his courtesy, two excellent photographs (Figs. 3 and 4) of the corona obtained by the Poulkovo expeditions at Omsk and at Sara are reproduced here. The main Poulkovo station was near us at Omsk, on State Farm No. 54, and its observers and the staff of the State Farm rendered us much assistance for which we are deeply grateful.

---

[1] A. H. Rosenthal, *Z. Ast.*, **1**, 115 (1930).

[2] Curtis and Burns, *Pub. Alleg. Obs.*, **6**, 95.

[3] B. Lyot, *C.R.*, **202**, 1259 (1936). Lyot gives 7891·6 ± 0·2A. as a new line. The observations of Curtis and Burns in 1925 do not seem to be recorded in any of the more recent lists of coronal lines. I assume provisionally their line at 7896 is the same as Lyot's, allowing for the relative inaccuracies of the measurements made in 1925.

The Formosa Earthquake of April 21, 1935

WITHIN a year after its occurrence, the reports on this destructive earthquake have been issued in a special volume (Supplementary volume 3, 238 pages) of the *Bulletin of the Earthquake Research Institute*. The memoirs (eleven in number) are written in Japanese, each being followed by a summary in English. The five reports are also in Japanese, but only one of them contains an outline in a Western language. Few works on any earthquake have been so admirably illustrated, for half the volume consists of 29 maps and 119 plates, each of the latter containing reproductions of two or three photographs, with titles in English as well as in Japanese. They represent the damage to villages and buildings, the buckling of railway lines, the fissures in roads and fields, and various aspects of the remarkable earthquake faults.

The recent seismic activity of the northern half of the island is described by Prof. N. Miyabe (pp. 1–9), who notes that, since the beginning of 1934, the frequency of minor shocks felt at Ari-san (near the centre of the island) showed a continual increase up to the time of the great earthquake at 7.2 a.m. on April 21 (April 20, 10.2 p.m., G.M.T.). From seismographic records, the epicentre was found to be in lat. 24° 20′ N., long. 120° 38′ E., and the depth of its focus about 10 km. below the land-surface. The earthquake was very destructive to life and property; 3,279 persons were killed and 54,792 houses destroyed. In seven villages in the Taityu district, more than 70 per cent of the houses were ruined, but, as several of the authors notice, this was mainly due to their poor construction, the walls being formed of *dokaku* or blocks of hardened clay and straw, and very much weaker than those of the wooden houses in Japan. Mr. R. Takahasi (pp. 120–140) notes that the greatest intensity of the earthquake was reached in two regions that coincide with the north and south branches of the earthquake faults.

According to Mr. Y. Otuka (pp. 22–74), there were two main faults along which displacement of the crust occurred. The northern or Siko fault is about 15 km. long and runs in a direction about N. 30° E. from Gabi-syô to Taitôsei. Along this fault, the west side rose in two places about 3 metres relatively to the other side, the horizontal displacement being quite insignificant. The southern or Tonsikyaku fault is about 12 km. long and its general trend about N. 60° E. The north-west side of this fault was, relatively to the other side, shifted 1–1½ metres to the north east. Shortly before the earthquake, a fault was traced running from Gabi-syô to Taian, and the earthquake faults lie close to and parallel to this line. Mr. Otuka records the interesting fact that, at two places, the fault-movement took place after the houses in which the observers lived were destroyed.

From August until December 1935, the after-shocks were recorded at a network of four stations at which Ishimoto acceleration seismographs were installed. Most of the epicentres, according to Mr. N. Nasu (pp. 75–86), lay on the west side of the faults, and the focal depths were usually about 10 km. or less. In many of the shallow-focus earthquakes (depth 0–5 km.), the epicentres were close to the fault, especially in the upheaved region on its west side. Mr. Nasu notices that this was also the case with the after-shocks of the Tango earthquake of 1927 that he studied with so much care. At Byôritu (Taiwan), where the after-shocks were frequent, the level of the water in a well was measured from October 1935 (N. Miyabe and S. Kawasima, pp. 93–95). On the curve representing the changes of level from October 30 until January 10, dots are placed corresponding to the times of the after-shocks, and these occur at every point at which the level varies in direction.

The buckling of railway lines during a great earthquake is due, as a rule, to subsidence of the ground or to the destruction of the embankments on which the rails are laid. Such buckling occurs in both horizontal and vertical directions. Mr. R. Takahasi (pp. 148–153) describes and illustrates several cases of sinuous buckling. These are confined to a horizontal plane and lie along the fault-zone or its continuation. The buckling thus seems to be due to the movement of the surface layer of the ground on one or both sides of the fault.

Immediately after the earthquake, repetitions of first order triangulation and first order levelling were carried out in the central area by the Japanese Land Survey. The former, begun in August and finished in December 1935, included 14 points, three of which by comparison with the previous survey in 1917 had shifted by 26, 33 and 44 cm. The levelling was repeated along a route, 270 km. in length, from Kiirun and Musya, and was begun in October 1935 and completed in the following March. In the interval since the preceding survey, it appears that one point rose 23 cm., while another subsided 68 cm. C. D.

Obituary

Sir Arnold Theiler, K.C.M.G.

THE death of Sir Arnold Theiler on July 24 at the age of sixty-nine years has removed from our midst one of the greatest and most practical exponents of veterinary science of the century. There was no man more cosmopolitan in his principles, nor indeed was there a veterinary surgeon who was more universally welcomed in every country within whose borders he set foot, than Sir Arnold. His modest demeanour and his forceful personality, together with his untiring patience and plodding disposition, made him welcome everywhere. A Swiss by nationality and a veterinary graduate of the University of Berne, Great Britain was lucky in having him as a worker within its Colonial domains; and it was a great day for the British veterinary profession when Sir Arnold was offered—and accepted—the honorary associateship of the Royal College of Veterinary Surgeons. It was also a great honour for the Royal Veterinary College in London, when Sir Arnold made the request to Sir Frederick Hobday, its principal, that he might complete, within its walls, the summary of the great work which he had collected together on the osteo-dystrophic diseases of bone. This shortly followed his lectures (which were also given in the Royal Veterinary College, at the request of the University of London), and it was another fortunate circumstance that the editor of the *English Veterinary Journal* was able to secure the publication of these lectures in his journal.

Born in Switzerland in 1867, Theiler went to the Transvaal as a doctor of veterinary medicine in 1891. He found the Boer farmers very difficult; their narrow ideas, which led them to think that the diseases of their cattle and sheep were punishment inflicted upon them by the Almighty, were very difficult to overcome. It was only when a severe outbreak of glanders among the horses in Pretoria, and a disastrous outbreak of rinderpest in their cattle, enabled him to demonstrate the value of scientific veterinary knowledge in checking these respective outbreaks, that his consummate patience and skill triumphed to the extent that President Kruger, realizing the great value of Theiler's help, appointed him Veterinary Surgeon to the Republic. The South African War temporarily checked his work, and, as a burgher, Theiler was appointed veterinary surgeon to the Staats Artillery, a position which he filled with credit to himself—all the time with his brain working and learning points which stood him in good stead afterwards in his combat against disease.

Returning to Pretoria after the War, Theiler's reputation made him *persona grata* with the British Army staff, who were quick to recognize his knowledge and ability; and he was given laboratory facilities at Dasspoort and provided with an adequate staff. Whilst there, he came in contact with Lord Milner and Mr. F. B. Smith, the Director of Agriculture; and eventually he was given practically a free hand, the result being the foundation of the greatest experimental veterinary laboratory in the world—at Onderstepoort. The Botha and Smuts Government gave him staunch support and, on the formation of the Union in 1910, Arnold Theiler became the first Director of Veterinary Research. In 1920 he organized the Veterinary Faculty of the University of South Africa, being appointed its first dean, a post which he held until his retirement in 1927.

Theiler's honours were many. In 1907 he had been created a C.M.G., and in 1914 the knighthood of this order became his; then the fellowship of the Royal Society of South Africa and the first grant and medal awarded by the South African Association for the Advancement of Science. He was also the first recipient of the Scott Medal of the South African Biological Society. He was an honorary D.Sc. of the Universities of Cape Town and Syracuse, and D.Phil. of the University of Berne.

Theiler's married life—always very simple—was a happy one, and he leaves behind a widow, two sons and two daughters, all of whom are making names for themselves in the world of science. His death has left a gap which it will be very difficult to fill; but his name will ever remain not only as a pioneer, but also as a creator, in the world of veterinary science.

Dr. Bernard Smith, F.R.S.

BRITISH geology in general and the Geological Survey of Great Britain in particular have suffered a lamentable loss through the death on August 19 of Dr. Bernard Smith. Since October of last year he had served as director of the Geological Survey and Museum in succession to Sir John Flett. Smith was not only a brilliant geologist but also a scientific worker of exceptionally wide outlook, and, as he had served for thirty years on the Geological Survey in varied districts and capacities, his knowledge of the geology of Great Britain was most accurate and extensive. He had a very lovable personality, being genial and sympathetic by nature, and his sound judgment carried him successfully through many difficult situations. He died at the comparatively early age of fifty-five years, while it might have been anticipated that he had at least ten years of active work to look forward to in the Government service. Up to a few weeks ago, he was in regular attendance at his office.

Smith was born in Grantham and had his preliminary education at King Edward VI School there. He passed to Sydney Sussex College, Cambridge, as a scholar, and graduated in the first class of the Natural Science Tripos, Parts I and II. He won the

Harkness Scholarship in 1906, having been a demonstrator in geology since 1904, and in 1906 also he entered the Geological Survey by competitive examination. For a time he worked in the Midland coalfields districts under Lamplugh, but he surveyed also in North Wales. When the Great War broke out he devoted much time to the study of British iron ores, on which subject he ultimately became a recognized authority; but he also gave much assistance to the Ministry of Munitions on many other subjects connected with British resources of economic minerals.

In 1920 Smith was appointed district geologist, and shortly thereafter proceeded to Whitehaven where he superintended the revision of the geological maps of the Cumberland coalfield and adjacent districts. He had already produced a notable monograph on the Cumberland hæmatite iron ores which soon passed into a second and revised edition, and is the standard work on that subject. The Cumberland coalfield is very complex in structure and was not well understood before the revision undertaken by Bernard Smith and his staff; but it may be said that it is now one of the best known British coalfields, and the new maps and memoirs leave nothing to be desired. His work in that district was much appreciated by the local engineers and mine owners, and his personal relations with all connected with the industry, even though they might differ from him in opinion, were always excellent.

In 1931 Dr. Smith succeeded Mr. John Allen Howe as assistant to the Director in London and was placed in charge of all the field work in England. He also arranged the North Wales exhibits in the new Museum of Practical Geology. His time was now principally occupied in administrative work, and in answering inquiries sent in by Government departments and by the public. In this respect he was a great success, and in due course he succeeded to the directorship of the Survey and Museum in October, 1935.

Smith's natural bent to field geology was shown by his text-book of "Physical Geography" (A. and C. Black, Ltd.) now in its third edition. He also wrote on the glaciation of the Lake District and of the Isle of Man and on the history of Cumbrian rivers. His official work was very varied, but his principal contributions to Survey literature were his "Iron Ores of Cumberland" and the memoirs on the Whitehaven coalfield which he edited and in large part compiled. He was awarded the degree of Sc.D. (Cambridge) in 1924, and the Bigsby Medal of the Geological Society in 1927. The Royal Geological Society of Cornwall conferred on him the Bolitho Medal in 1933. In 1933 he was elected fellow of the Royal Society, and he served on the Council. In 1935 he delivered the Cantor Lectures on "Underground Water Supply" at the Royal Society of Arts; and he was actively engaged in the work of the Inland Water Resources Committee of the Ministry of Health. He served also on the National Committee of the Union of Geodetics and Geophysics and was a member of the Sub-Committee on Vulcanology and Hydrology.

Dr. H. A. D. Jowett

IN a characteristic appreciation of the late Sir Henry Wellcome, published in *The Times* of August 3, Prof. H. E. Armstrong points out that he chose his men with great shrewdness. It is with great regret that we have to record, so soon after the loss of Sir Henry Wellcome himself, the death of one of these chosen helpers, as the result of a motor accident on Monday, August 10. Dr. Jowett was born at Dorchester in 1870, but received his education at the Royal Grammar School, Lancaster, and remained in that town until 1891, when he gained a Bell Scholarship offered annually by the Pharmaceutical Society and became a student in the Society's College in Bloomsbury Square. He took his diploma in due time, along with most of the College prizes, and was awarded the Redwood Scholarship, which gave him entry to the Society's Research Laboratories, where he remained until 1896, working on aconitine and atisine, the latter being the subject of the thesis which he presented successfully for the London D.Sc.

In that year, Jowett became chief assistant in the newly-founded Wellcome Chemical Research Laboratories. There he spent ten busy and fruitful years, during which he made contributions of the first importance to our knowledge of the chemistry of the alkaloid pilocarpine, the hormone adrenaline and some of the naturally occurring glycosides and anthraquinone derivatives, chrysophanic acid, emodin and aloin. The work on pilocarpine and adrenaline was not only important in itself, but also it stimulated interest in the glyoxaline nucleus and in pressor amines, subjects which were to occupy both chemists and pharmacologists in the Wellcome Laboratories for some years to come. Jowett also began during this period those interesting investigations on the effect of change in structure in the tropeines on their mydriatic action.

In 1906 Jowett left London for Dartford to inaugurate the Experimental Department of the Wellcome Chemical Works, and a year later was appointed works manager, but was still able for some years to continue with collaborators the researches started in London. Having acquired a considerable reputation as an investigator, Jowett must have accepted his new post with some misgivings, but he soon justified his choice, and under his management the manufacture of fine pharmaceutical chemicals increased slowly but surely, and when War broke out in 1914 the works were ready to take a great part in the manufacture of those essential synthetic drugs which the nation had up to that time been content to import. In a very short time British equivalents for such complex drugs as 'salvarsan' and 'neosalvarsan' were being manufactured, and numerous other fine chemicals were added as required.

This development has continued steadily to the present time, and in this connexion it is only necessary to refer to the rapidity with which the manufacture of new products, such as insulin, ephedrine and ergometrine, has been undertaken and to the successful research work on cardiac glucosides and ergot alkaloids now in progress in the experimental laboratories at Dartford, to show that his inspiring personality was as vigorous as ever after forty years service to the Wellcome Foundation.

Dr. Jowett was not only skilled in chemistry, administration and the management of men: he became a motorist almost as soon as motor-cars were available; he was a keen golfer and an enthusiastic Wagnerian, and in recent years he developed a great interest in local government, becoming a member of the Dartford Borough Council, where as chairman of the Health Committee his administrative experience and scientific knowledge were of great service to his fellow citizens.

Dr. Jowett's friends are not likely to forget his achievements, but they will remember even more vividly his kindly and lovable personality.

WE regret to announce the following deaths:

Prof. F. Breinl, professor of hygiene in the German University of Prague, an authority on bacteriology, on July 29.

Prof. B. G. Cormack, emeritus professor of botany in the Anderson College of Medicine, Glasgow, on August 19, aged seventy years.

Dr. W. G. Plummer, assistant keeper in the Science Division (Physics and Geophysics) of the Science Museum, South Kensington, on August 2, aged thirty-eight years.

W. Rintoul, O.B.E., a director of research of Imperial Chemical Industries, Ltd., formerly manager of the Ardeer factory of Nobel's Explosives Co. Ltd., on August 24, aged sixty-six years.

News and Views

Synthesis of Vitamin B_1 (Antineurin)

SINCE the realization that the molecule of vitamin B_1 contains two heterocyclic rings, a substituted pyrimidine and a substituted thiazole, intensive research has been directed towards establishing the positions of the substituent groups and the method of combination of the two rings. According to a paper of which a brief abstract appears on p. 372 of this issue, Prof. Williams and his collaborators at Columbia University have now succeeded in isolating a compound which is chemically and physiologically identical with the natural vitamin. Several groups of workers in Great Britain and Germany have been working at the same problem, but they will doubtless be among the first to congratulate the American chemists concerned on a brilliant and important piece of organic synthesis. It may be noted that this achievement means that, with the syntheses of ascorbic acid, lactoflavin, vitamin D and vitamin B_1, four vitamins have now been produced from completely inactive organic reagents by purely chemical means.

New Fossil Anthropoid Skull from South Africa

A DISCOVERY is announced from South Africa which, if first impressions are confirmed by more detailed examination, may go far towards clearing up a point which has been a matter of acute anthropological controversy for more than a decade. Dr. Robert Broom, of the Transvaal Museum, and his colleagues, it is reported in a dispatch from the Johannesburg correspondent of *The Times* in the issue of August 26, have discovered in the Sterkfontein caves near Krugersdorp, a natural cast in limestone of the brain of an advanced type of ape and a number of fossilized bones of the skull, including jaws and teeth. It is anticipated that this new evidence will prove of importance in its bearing upon the status of the phylogeny of man and the great apes, and more especially on the position of the Taungs skull. It will be remembered that, when that fossil was found in 1924, some doubt was expressed as to how far the approximation to the human type in its characters stressed by Prof. Raymond Dart, by whom it was discovered, was due to its immaturity. The young of the chimpanzee, it was pointed out, is well known to exhibit pseudo-human characters, which disappear as maturity approaches; and it was agreed that the Taungs skull was that of an individual of not more than six years of age. As the Sterkfontein specimen, it would appear, is adult, a comparison with the Taungs skull may determine these uncertainties, and at the same time afford an indication of the relation of these fossil types to existing anthropoids as well as to early forms of man.

Roman Leicester—a National Asset

THE fate of Roman Leicester, which now hangs upon the decision of the City Council, is a problem in which the nation is no less deeply concerned, though from a slightly different point of view, than the city itself. A site in the heart of the city's oldest relics, purchased at a cost of £24,000 for the erection of public baths, has yielded on excavation remains of the Roman period, more particularly of the forum, the centre of municipal life, which in certain respects are unique (see NATURE of July 11, p. 69). While on one hand the local authority may allow due weight to the advantage to Leicester in the possession of this unique and irreplaceable monument of the past, yet local pride must inevitably be tempered by a sense of the duty of trustees of public funds; on the other hand the nation at large is a custodian of such treasures as this for the benefit not only of contemporary archæological studies, but also of posterity. The most meticulous records of excavation, however valuable for scientific study, cannot take the place of relics of antiquity which have been destroyed. Apart from the educational appeal of the buildings in their original relation, and so far as possible, in an appropriate setting, they will afford the scholar a constant inspiration to further research, as well as provide a source of evidence for correcting or reconstructing theory in the light of later knowledge, such as never can be derived from a written record, photograph or drawing. The excavations now in progress may reinforce the argument, or should the City's decision be adverse to preservation, justify a delay, which will then be urged, pending an appeal for funds from outside sources for the complete excavation of the site in the coming year. The conflict between duty to local economies and the preservation of antiquities, which are national in their interest, is one which is likely to arise with increasing frequency in view of the rapid development of urban and suburban properties now taking place. When such developments affect relics of wide historic and scientific interest, as at Leicester, it is a question whether national funds should not be called on to assist.

Potters of Lincoln

MUCH interest is attached to the discovery of a Roman potter's kiln at Lincoln, fully loaded with a light cream ware, and fired, but unopened. It affords evidence that an industry, which discoveries in 1932 have shown to have been in existence here in the Middle Ages, was also extensively practised in the Roman period. Quite possibly, as 'Pottergate Arch' nearby, and the occurrence of 'Pottergate' as a street name in the thirteenth century would suggest, the industry may have survived throughout the interval between medieval and Roman times with little or no interruption. The kiln was discovered, it is reported in *The Times* of August 21, on a site in Cathedral Street. It contained vessels of the mortaria type, the large shallow basins with a heavy rim, in which the Romans used to grind their food. The kiln was a hole in the ground four feet long and two feet wide, with a well-fired wall on two sides. It was roofed over with a whitish clay mixed with sand; and it contained four stacks of pottery, which had been considerably crushed. Curious short pipes, of which the use is obscure, were also found. Many of the vessels were stamped with the potter's mark, which, when deciphered, should afford a clue to the distribution of Lincoln pottery in Britain. The medieval pottery, which was found in this area, was attributed to the fourteenth century. No doubt the potters of that date drew their clay from the same source as their Roman predecessors. This in itself would be sufficient to account for the persistence of the industry in this area.

Minoan Influences in Ancient Syria

SIR ARTHUR EVANS, commenting on the results of Sir Leonard Woolley's recent archæological investigations in Syria (see NATURE of July 4, p. 20 and August 8, p. 235), pronounces the Minoan impact on inner Syria at so early a date, for which the ceramic relics from Tell-Atchana afford evidence, as "a new historic fact of far reaching importance and revolutionizing all previous ideas". It is, he points out in *The Times* of August 19, a step forward of at least two centuries; for although there are no actual imports from Minoan Crete, the starting point in repeated examples of pottery reflecting Cretan models must certainly touch 1700 B.C. Sir Arthur bases this conclusion on the chronological datum of remains of cups, of somewhat thin make, showing white rosettes on a black ground, recalling the "egg-shell ware" bowls of the great age of Minoan Crete of the Second Middle Minoan period, which goes back to the eighteenth and nineteenth centuries, but in Syria equating with the succeeding Third Middle Minoan style. At the same time, mixed influence is to be seen in the combination of arcaded zones, characteristically Minoan, with highly conventionalized ducks, which find a parallel in early Palestine, while one of the sherds depicts an uprearing goat charged by another, whereas animal designs were excluded from the vase painting of Cretan Palace art. In concluding with an analysis of motifs, which point to a fusion of Cretan and indigenous religious and symbolic ideas, relating to the cult of the double axe, and reference to tradition of a royal alliance with Cyprus, Sir Arthur holds out the alluring possibility that the spade may yet uncover a royal sepulchre at Tell-Atchana.

Special Exhibit at Ipswich Museum

IN 1917, Mr. Reid Moir announced the discovery of flint implements, mammalian and human bones, and fragments of rough pottery, in the lower of two superposed 'floors' in a brickfield of Messrs. Bolton & Co. at Ipswich. These occupation levels occurred in sand, and were overlain by a considerable thickness of hill-wash, while the excavations carried out showed that the now dry valley in which the discoveries were made has been deepened by erosion since the floors were occupied by man. Similar results were obtained, at a later date, by Mr. J. P. T. Burchell, in his researches at Ingress Vale in the lower Thames Valley. Here, at the base of an extensive section of sub-aerial loam, surmounted by a hill-wash containing rafts of Coombe Rock, was found a prolific floor, with flint implements, flakes, and fragments of primitive pottery. The third site, where a similar association of relics occurred, was discovered and investigated by Mr. and Mrs. MacAlpine Woods in a dry valley at Bovey Lane, Beer, Devon. In this case, a hill-wash, some 11 ft. in thickness, contained large numbers of flint artefacts, a few examples of bones and teeth of animals, and some pieces of rough pottery. Through the kindness of the discoverers, the Ipswich Museum now possesses representative series of the specimens mentioned, and is making a special exhibition of them. The matter is of considerable interest to archæologists as, in each case, the flint implements may be said to resemble, in their forms, those of Lower and Upper Aurignacian times, and are not associated with any microliths. Moreover, there seems good reason to believe that the widespread deposits in which the relics were embedded are of relatively considerable antiquity, and represent the results of geological activity, including an epoch of low temperature, in eastern and southern England.

Current Science

WITH the publication of its July issue, our Indian contemporary, *Current Science*, enters upon its fifth year. Founded to supply an obvious need in the scientific renaissance of India, *Current Science* is almost unique in that its editor is assisted by a board comprising the majority of the best-known Indian men of science. The July issue contains much of interest not only to India but also to the West. The leading article comments on the inauguration, by his Excellency the Viceroy, of a Nutrition Advisory Committee. The outstanding investigations of Sir Robert McCarrison in Coonoor have in recent years focused the attention of Indian public opinion upon the importance of adequate feeding for national efficiency. Inadequate nutrition, combined in many areas with endemic malaria, is known to be the cause of the poor physique of many classes. The Royal Society is now assisting in the investigation of the intricate problems of malaria control, and will doubtless co-operate with this new Advisory Committee. Another article in the July issue, of more than local interest, is the summary of a lecture given by Prof. Birbal Sahni on the Karewas of Kashmir, where the geology of the Karewas series in the Himalayas is discussed from the point of view of the botanist. We congratulate the editor of *Current Science* on the high standard of the journal, which, if maintained, ensures its continued success.

Philosophy and Quantum Theory

IF philosophy is, as Descartes claimed, the 'universal science', it should be able to assimilate all new discoveries in the special sciences. There was not much difficulty in dealing with classical physics. When the theory of relativity was put forward, it was soon found that philosophical ideas could be rearranged to find it a place, and even a welcome, but what is to be the attitude to a theory which denies continuity and determinism ? An attempt, admittedly incomplete, to answer these questions has been made by R. Dugas ("La méthode dans la mécanique des quanta". Actualités scientifiques et industrielles, 283. Paris : Hermann et Cie., 1936). Following Meyerson, complete indeterminism is rejected, and replaced by aggregates ruled by laws of probability. If there is no law, there is no science. Other difficulties arise when we try to discover the basis of Schrödinger's equation. Are we to say that our equations know more than we do, and that, without understanding them, we can rely upon them to furnish the correct results ? Are we to believe in *panmathesis*, and in a universe in which electrons and matter have no real existence, but are merely names for mathematical symbols ? The trouble with questions such as these is that all the available evidence appears to point to the conclusions that are repugnant to common sense.

Photomicrographic Reproduction of Scientific Papers

FOLLOWING on the formation of the Documentation Division of Science Service, a programme of testing mechanical methods of applying photomicrographic duplication of scientific literature is being developed, including a camera for copying upon 35 mm. film, supplementary apparatus such as a book holder for the camera, film container, etc., a reading machine, microfilm viewer, projection printer, and developing and processing apparatus for 35 mm. microfilm and paper projection points. Procedure has already been developed for the publication of scientific material otherwise unable to receive publication in full. Editors of journals or institutions deposit typescripts of those papers or portions of papers which they are unable to publish promptly or completely. With an abstract or summary, they publish a statement that additional matter, illustrations, tables, etc., are available on request from Science Service if the document number is stated and the price remitted. The document is assigned a number by Science Service and on receipt it is photographed on 35 mm. film master negative. The original document is then deposited elsewhere as a safeguard. The photomicrographic duplication is economical when up to twenty-five copies at a time are required and has the further advantage that the document is continuously in print as the negative can be used to supply a copy on demand at any time.

THE relation of microfilms or photo-copies prepared in this way to priority in scientific discoveries has been raised. Opinion is expressed in a note issued by Science Service that microfilm or photo-copy publication is a printed publication in the true sense, and that by considerably reducing the time between the submission of a paper to a journal and the date of publication of the discovery announced therein, this type of publication will be of great assistance in eliminating controversies such as have arisen in the past concerning individual claims for priority in making discoveries. If any doubt exists as to whether photomicrographic publication is a 'printed publication', it is urged that this doubt could be removed by scientific societies merely agreeing among themselves that, in so far as priority in their fields is concerned, photomicrographic publication should be accorded the same weight and effect as publication in a printed journal.

Wind Erosion in South Australia

WIND erosion is becoming an increasing danger in the semi-arid regions which form the world's chief granaries. In North America, the Argentine and to a less extent in Russia, the fertile prairie soils are rapidly being swept away as the result of destroying the original grass cover. A similar fate is overtaking vast pastoral regions in South Australia, due to overstocking. The gravity of the situation is revealed in a note by F. N. Ratcliffe, received from the Commonwealth Council for Scientific and Industrial Research. The worst erosion has been in the 'bush' country, where twelve drought years have so lowered the stocking capacity that overstocking on established farms is now almost unavoidable. Rabbits have added to the evil, the vegetation cannot recover after grazing, and natural regeneration of both shrubs and grasses has virtually ceased. Large areas have become barren deserts, and no measures are available for their reclamation. The evil might be checked by adopting a lower stocking policy; but the only hope for the already denuded areas is to introduce perennial exotic plants capable of stabilizing the large sand drifts, and withstanding rabbits and a very low and uncertain rainfall. The chance of discovering such plants is remote, and even if discovered, "there would remain the problem of their dissemination through vast areas with no regular growing season and an unimproved capital value rarely exceeding 2*s*. per acre".

Mining in Canada

WE have received the Report of the Department of Mines of the Dominion of Canada for the fiscal year ended March 31, 1935, and taken as a whole it may be said to be thoroughly satisfactory. The Report shows that the rise in the price of gold has caused renewed activity in that industry and states that "Canada's gold industry is contributing to the prosperity, not only of the communities in which operations are centred, but to the industrial life of the nation as a whole". Canada apparently is also reopening some of the silver camps for which it was famous a few years ago, but the "Department's work in fuels and non-metallics is becoming of increasing economic importance", and there has been a relatively small number of ore treatment investigations in connexion with base metal ores. There are full reports of the various divisions of the Department of Mines, commencing with a Bureau of Economic Geology, the National Museum of Canada and Mines Branches proper, together with an Explosives Division, an Editorial Division and an Accounting Division, which latter shows that something like a million dollars was available for the expenditure of the Department of Mines, and that nearly all of it was utilized. It is interesting to note that the Fuels and Fuel Testing Division was busily engaged throughout the year in question.

Cotton Research in India

INDIA is the second largest cotton growing country in the world, and the importance of the industry led the Indian Cotton Committee to set up a Technological Laboratory at Matunga some ten years ago. Research work and tests of direct importance to the cotton breeder, merchant and mill owner have been carried out in collaboration with the provincial agricultural departments, and a brochure has just been published by the Committee giving a full account of the activities of the Laboratory since its inception (Bombay: Indian Central Cotton Committee. 2 rupees). The two main objects of the work are to undertake spinning tests on improved varieties of cotton, and to establish relationships between the measurable fibre characteristics and the spinning quality. This second object aims at dispensing with the necessity of making spinning tests on large numbers of new strains, as it is hoped to be able to assess the performance of the cotton from a knowledge of its fibre properties. The development of the work may be judged from the fact that during 1933–34, 166 samples were tested in connexion with trade and technological problems, compared with only 28 in 1924–25, while as regards agricultural samples, 366 were tested in 1933–34, compared with 46 in the 1924–25 season. The problem of averting the possible danger of the introduction of the cotton boll-weevil through imported American bales has been successfully attacked. A satisfactory method of fumigation has been developed, and legislation enacted to ensure that all cottons imported from America are so treated. The brochure concludes with a complete list of publications issued from the Laboratory since 1925.

The Science Museum Library

ON entering a library for the purpose of obtaining information on a given subject, the first things the visitor wishes to know are what books or pamphlets the library possesses relating to the subject, and how is he to obtain them. There are usually card indexes available, but even with these at his disposal the reader may well be at sea unless he possesses a key to the system on which they are arranged. The publication of a new edition of the "Classification for Works on Pure and Applied Science in the Science Museum Library" (London: H.M. Stationery Office. 5*s*. net.) provides such a key to the finest science library in Great Britain. It should be studied by every one who uses the Library. It contains an explanation of the Universal Decimal Classification of the International Institute of Documentation in use at the Library, a list of about six thousand classes into which knowledge is divided for the purpose of indexing, and a copious alphabetical index comprising some five thousand entries. In the preface to the "Classification", Dr. S. C. Bradford says: "The titles on the cards in the Subject Catalogue are numbered and arranged in accordance with the Universal Decimal Classification. Under each number the titles are in chronological order. To ascertain what books the Library possesses on a given subject, readers are recommended to look first in the index, and then refer to the classification, before consulting the cards." By following this advice, those not already familiar with the system used in the Science Museum Library will undoubtedly save themselves both time and labour. It may be added that, in the last Report on the Science Museum, it was stated that the Library now possesses 252,515 volumes, the total of periodicals currently received is 9,468, while the Subject Matter Index contains 2,248,423 references.

Progress in France of Electricity Supply

AN account of electricity supply in France appears in *World Power* of July, as a translation of a paper in *La Journée Industrielle*. In 1923 the total installed capacity of electrical generating stations was 4½ million kilowatts. This increased to 10½ million in 1935. There are 15 thermal and 5 hydro-electric stations each having a capacity greater than 100,000 kw. The capacity has increased more rapidly than the output owing to the necessity of keeping a large reserve of power to meet sudden fluctuations in the consumption. In Paris, for example, the rate of consumption varies between 50,000 kw. at 3 a.m. and 340,000 kw. at 5 p.m. The rate of consumption of hydro-electric power is now greater than that of thermal power. It is noteworthy that the total length of the distributing lines is increasing more rapidly than the consumption of power. This is due to the increasing number of small consumers and to the fact that, as the supply service is extended to the more remote regions, longer lines are needed to reach new users. At present it is necessary to lay 46 metres of low tension line, on the average, to supply each new consumer, whereas in 1923 the length of line required was 13 metres. The large industries consume 7,100 million kwh. per annum and electrochemistry and electrometallurgy together take 2,200. Lighting and domestic supply take 1,800, small industries 1,000 and traction 900. There are now 35,369 communes supplied with electricity, and only about 2,600 not so provided.

Protection against Gas Attacks

THE Socialist Medical Association has issued a booklet entitled "Gas Attacks: Is there any Protection?" (London: Lawrence and Wishart, Ltd. 6*d*.). It is maintained that air-raiders are certain to penetrate our defences, and will not hesitate to employ a combination of high explosives, fire and gas in their attacks, against which the only efficient protections are respirators and gas- and bomb-proof self-contained dug-outs. The booklet issued by the Home Office, "Anti-Gas Precautions and First Aid for Air-Raid Casualties", is criticized, and is considered to give an incorrect impression of the dangers of war gases and possibilities of protection, and that the defences proposed, even if they could be generally adopted, would be inadequate. Dr. Sommerville Hastings contributes an introduction, the nature of the gases employed and their effects are described, and the available means of protection and the treatment of gas casualties are discussed.

Bulletin of the Metchnikoff Institute of the Ukraine

THE Metchnikoff Institute of the Ukraine has commenced the issue of a monthly bulletin (*Bulletin de l'Institut Metchnikoff*) devoted in the main to bacteriological and immunological papers from the Institute, written in French, English and German. In an editorial note to the first number (April 1936), it is remarked that until 1917 bacteriology had made slow progress in Russia, but that since that time many new institutes have been established and the active roll of bacteriologists and epidemiological experts has very greatly expanded. The nineteen extremely brief papers published in the first number are written in summary fashion without bibliographies, but any efforts that facilitate the introduction of Russian work to non-Russian readers are to be heartily welcomed.

The *Aquarist and Pond-Keeper*

THE *Aquarist and Pond-Keeper*, incorporating the *Reptilian Review*, in the March–April number, 1936, has various improvements, including a new cover design. Specially striking is a collection of photographs occupying two pages, which with the illustrations to the article on reptile hunting in Britain by A. E. H., depict the whole of our native species of reptiles and batrachians. Mr. E. Bridgstock-Choat, honorary curator of the Erith Museum, contributes an article entitled "The Pond Hunter", which will be continued, and papers from various other workers deal with fishes, fish-breeding, ponds and water gardening and various allied subjects.

Official Statistics

ATTENTION may be directed to the publication of the Guide to Current Official Statistics for 1935 (London: H.M. Stationery Office. Price 1*s*.). The arrangement is the same as in previous years. The greater part of the volume is occupied by an alphabetical range of subjects with reference to the appropriate publication. This is followed by a list of publications arranged under departments. The volume is invaluable for quick reference, and reveals the great range of matters on which statistical and other official information is available.

Post-graduate Medical Research

THE Medical Research Council has decided to institute a series of studentships and fellowships to encourage young British medical graduates towards becoming investigators in those branches of medical science which are concerned directly with disease as it occurs in human beings. Six post-graduate studentships are therefore offered for medical graduates who have already held house appointments and are strongly inclined to a career in clinical science or experimental pathology. Each selected student will receive an inclusive grant at the rate of £200 per annum, during a period not exceeding twelve months, while undertaking approved courses of study in Great Britain such as may be regarded as best calculated to advance the student's training in methods of research. Four research fellowships are also offered for candidates of similar qualifications who have already had some experience in research methods. Each fellowship will be tenable for one year at the value of £250 per annum, and will be renewable in approved instances at the rate of £300 per annum for a second year. Further information can be obtained from the Secretary, Medical Research Council, 38 Old Queen Street, London, S.W.1.

Fireball over Yorkshire

THE occurrence on August 18 at about 22^h 23^m (Summer Time) of a brilliant object, evidently a fireball or particularly bright meteor, has been referred to by several correspondents in the *Yorkshire Post*. The accurate observation of the apparent path of a meteor requires a trained observer, and it is to be expected that accounts supplied by casual eye-witnesses are often vague, conflicting, and quite unreliable for the data required to fix the real path above the earth. It seems, however, very probable that the fireball which lit up the countryside from which it was seen (including North Yorkshire, Derbyshire and Westmorland) was associated with the Perseid shower of meteors. This shower, which provides a high maximum frequency of meteors between August 10 and 12, is really operative from about mid-July until after mid-August; during this period the radiant point moves progressively from a position at about R.A. 1^h : Dec. +50° to R.A. 4^h : Dec. 65°, or from a position in the constellation Andromeda, through Perseus (which gives the shower its name) to Camelopardus.

The Night Sky in September

THE night sky of September offers a rich variety of objects for observation with slight optical aid. Some of the most attractive of the constellations are visible; there are star fields of the Milky Way, the Andromeda Nebula, the variable star, Algol, the Pleiades, some of the best known double stars and the largest two major planets. Between the first and last days of the month, the days shorten in the latitude of London by nearly two hours. On Sept. $23^d\ 5^h$ the sun enters, at the autumnal equinox, the sign Libra. Full moon occurs on Sept. $1^d\ 12\frac{1}{2}^h$ and again, as the Harvest Moon, on Sept. $30^d\ 21^h$. Of the planets to be observed, Venus still sets in the early twilight, but Jupiter is a bright object low in the south-west during the early evening. There is yet time, though very limited, for observing some interesting phenomena—transits, occultations and eclipses—associated with the four inner satellites. Particulars will be found on p. 615 of the *Nautical Almanac* for 1936. Saturn is above the horizon all night; on September 12 it is in opposition at a least distance from the earth of about 800 million miles. The rings appear nearly closed, the minor axis subtending an angle of only $1\frac{1}{2}$ seconds of arc. Mars is a morning star, and will be in conjunction with the bright star Regulus on September 24, when the angular distance between planet and star is less than 1°. Uranus is in Aries, and can be found near the 6th magnitude star ω Arietis, which the planet resembles when viewed with binoculars; but a 2- or 3-inch telescope will show the planet's disk of $3\frac{1}{2}''$ in diameter. The light variation of Algol (β Persei) may be observed near the following times of minima: Sept. $3^d\ 3^h$, $6^d\ 0^h$, $26^d\ 2^h$, $28^d\ 23^h$, Oct. $1^d\ 19^h$ (add 1^h to convert to Summer Time). The following double stars are suitably placed for observation during September: α Herculis (separation of components $4\frac{1}{2}''$), ε Lyræ ($3'$ separation for the wide components each of which is a double of $2\frac{1}{2}''$ and $3''$ separation respectively), β Cygni ($34''$) and γ Delphini ($11''$).

Announcements

PROF. MAX PLANCK, president of the Kaiser Wilhelm Society for the Advancement of Science, has been nominated doctor *honoris causa* by the Faculty of Philosophy of the University of Graz.

THE 1936 American Physical Education honorary award for achievement has been divided between the twin brothers, Dr. Edgar and Dr. Edwin Fauver, directors of physical education at Wesleyan University and Rochester University, respectively.

ON the occasion of the recent celebration of the twenty-fifth anniversary of the German Statistical Society the following were nominated honorary members: Prof. Sigmund Schott, director of the Mannheim Statistical Office; Dr. Friedrich Prinzing, of Ulm; Dr. Kovacs, president of the Hungarian Central Statistical Office, Budapest; and Dr. Savorgnan, president of the Italian Central Statistical Office, Rome.

DR. WILLIBALD SCHOLZ, professor of neurology and psychiatry at Munich, has succeeded the late Prof. Spielmeyer as director of the Department of Cerebral Pathology of the German Research Institute of Psychiatry, Kaiser Wilhelm Institute, Munich.

A NUMBER of public health courses have been instituted in Holland for training civilians in protecting themselves against attacks from enemy aeroplanes.

A SIX-year study of the role of diet in the last half of adult life will be undertaken at the New York State College of Agriculture at Cornell University. The Rockefeller Foundation has contributed 42,500 dollars to the support of the study.

THE second Italian Congress of Radiology will be held at Modena on September 20–21 under the presidency of Prof. Ruggero Balli, director of the Institute of Radiology. Further information can be obtained from the general secretary, Dr. Marco Lenzi, Istituto di Radiologia, Modena.

PROF. PAVLOV'S widow has presented the first batch of papers formerly belonging to her husband to the archives of the Academy of Sciences of Soviet Russia. They consist of about 2,500 letters from Russian and foreign men of science. Most of them relate to the years following the Revolution, while among the earlier ones are several from Metchnikoff and other famous men of science who corresponded regularly with Pavlov.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

An assistant (III) at the Ditton Laboratory, East Malling, Kent (refrigeration)—The Superintendent, Ditton Laboratory, East Malling, Kent (August 31).

Three inspectors (agricultural and live-stock) in the Department of Agriculture for Scotland—The Secretary (Establishment Branch), Department of Agriculture for Scotland, York Buildings, Queen Street, Edinburgh, 2 (September 1).

A civilian education officer in the Royal Air Force Educational Service—The Secretary (A.E.), Air Ministry, Adastral House, Kingsway, London, W.C.2 (September 14).

A visiting tutor for educational psychology in the Catholic Training College for Women, Cavendish Square, London, W.1—The Principal.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 369.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Structure-Factor Graphs for Crystal Analysis

WHEN unit cell and space group have been determined in crystal analysis by X-rays, the investigator tests various configurations of the atoms in the unit cell in order to obtain one which explains satisfactorily the observed strength of the diffracted beams with various index-triplets (*hkl*). For each configuration and each reflection (*hkl*), an appropriate 'structure-factor' can be calculated by the laws of optical interference. Large structure-factors correspond to strong reflections, and small structure-factors to weak reflections.

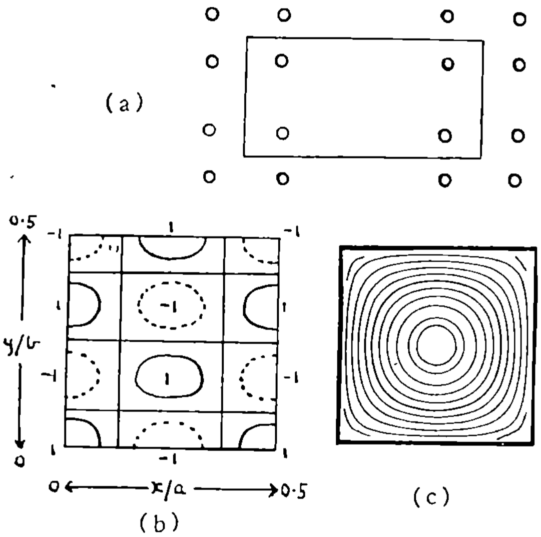

FIG. 1.

Once an approximation to the structure has been obtained, the fixation of the precise atomic positions is readily carried out by Fourier synthesis. The search for an approximate structure, however, is often extremely laborious, since in most cases a method of trial and error has to be used, and the structure-factor has to be computed for each tentative configuration. It is the purpose of this note to point out how greatly this labour is reduced by the use of *contoured graphs* of structure-factor.

It is usual to consider the projection of the structure on each face of the unit cell in turn, using the reflections around the corresponding zone in each case. 'General' reflections can then be used to test the structure so deduced. Although the number of space-groups is large, the number of symmetry types in the plane groups is restricted. A few formulæ for the structure-factor cover all cases.

As an example, the symmetry scheme shown in Fig. 1 (*a*) frequently appears in projections of monoclinic crystals on '*a*' or '*c*', and of orthorhombic crystals. An atom with co-ordinates x, y, along with the three other atoms to which it is related by the operation of the symmetry elements, gives a structure factor $4\cos(2\pi hx/a)\cos(2\pi ky/b)$ for the reflection ($hk0$). The function $\cos(2\pi hx/a)\cos(2\pi ky/b)$ is plotted in Fig. 1 (*b*) for the case $h = 2$, $k = 3$. In the graphs actually used in analysis contours are drawn for intervals of 0·1, but in this small-scale sketch only the zero lines and contours for 0·5 have been drawn. In the complete graph each small cell contains contours like those in Fig. 1 (*c*), suitably modified in horizontal and vertical scale. A set of graphs is prepared for all low values of h and k.

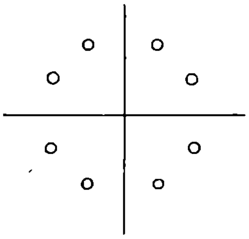

FIG. 2 *a*.

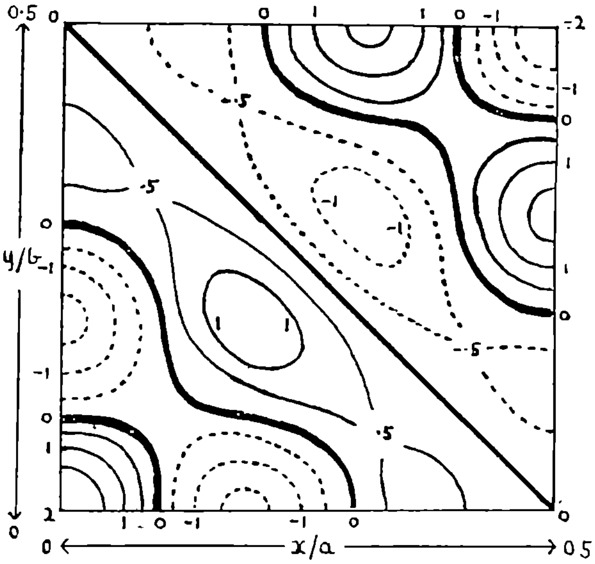

FIG. 2 *b*. Contours of the function $\{\cos(4\pi x/a)\cos(6\pi y/a) + \cos(6\pi x/a \cos(4\pi y/a)\}$.

When an atomic configuration is being tested, the x/a and y/b co-ordinates of its atoms are plotted on a transparent sheet which fits over the graphs. Structure-factors can be read by inspection to two figures, an amply sufficient accuracy. The principal merit of the graphs, however, is that the investigator can judge how the tentative configuration should be modified in order to make its structure-factor correspond to the observed value for each reflection, since the effect of moving an atom in a given direction and by a given distance is shown by the graph. The advantage of being able to do this will be appreciated by anyone accustomed to X-ray analysis.

By moving the origin from centre to corner of a small cell, the same graphs give values of $\sin(2\pi hx/a)\sin(2\pi ky/b)$. A single set of graphs, in fact, covers all cases of monoclinic and orthorhombic crystals for which the projection has a rectangular outline and a centre of inversion.

The advantage of the graphs is even greater in projections of tetragonal and hexagonal symmetry, when the atoms may be in groups of eight or twelve. The (230) graph for the tetragonal complex of Fig. 2 *a* is shown in Fig. 2 *b*. Such a graph considerably facilitates the adjustment of atomic positions. There are plateaux, for example, where the contribution of an atom varies very slowly, so that atoms in these regions give an approximately known contribution and attention may be concentrated on other atoms in 'sensitive' positions.

Trial has shown that analysis can be much more rapidly carried out with the graphs than by processes of calculation.

Molecular State of Proteins in Mixtures and Concentrated Solutions

BY means of the Svedberg high-speed ultracentrifuge it is possible to analyse mixtures of different molecular species, since the sedimentation involves a partial separation of the different sizes present. The concentration of the components may therefore be calculated from the sedimentation diagram. But during the study of protein mixtures in the ultracentrifuge it has often been observed that the concentration of the different sedimenting molecules thus calculated were not the same as those determined analytically. Generally the apparent concentration of the faster sedimenting molecule was smaller, when calculated from the sedimentation diagram, whereas it was higher for the slower sedimenting molecule. McFarlane[1], who first studied the problem on some artificial serum mixtures, thought that the effect was due to some specific interaction between the albumin and the globulin. Later, R. A. Kekwick and I studied some mixtures of serumalbumin and lactoglobulin. In this case serumalbumin, the faster sedimenting molecule, is found in too low concentration, and the lactoglobulin is found in too high concentration. From these experiments I concluded that the phenomenon was caused by some medium effect produced by the slower sedimenting protein molecules on the faster sedimenting ones, and that the effect was due to a real dissociation of the faster sedimenting molecules. If this is true, one would expect that it would be possible to produce the effect by means of lower molecular substances related to proteins, such as amino acids, polypeptides and protamines.

For the first two groups of these substances there was a measurable although very small effect. In the case of the protamine studied (clupein) the effect was very strong with serumalbumin, where it gave rise to new molecules with s_{20} (= sedimentation constant) of about 1×10^{-13} besides the ones with the normal $s_{20}(4 \cdot 5 \times 10^{-13})$. If we call the serumalbumin molecules with the normal s_{20}, *A*, and those of the dissociated serumalbumin, *B*, then the concentration ratio between these as calculated from the sedimentation diagram was: for a 5·3 per cent clupein solution $B/A = 1 \cdot 58$, for a 2·65 per cent solution $B/A = 0 \cdot 90$ and for a 1·1 per cent solution $B/A = 0 \cdot 36$. From these figures it is seen that the effect is by no means negligible since the dissociation product of serumalbumin in the more concentrated clupein solution is present in higher concentration than the undissociated serumalbumin. It is also very remarkable that all the sedimentation diagrams show only the presence of molecules with $s_{20} = 1 \times 10^{-13}$ and $s_{20} = 4 \cdot 5 \times 10^{-13}$ (besides a small amount of some association products); this probably indicates that the dissociation process always gives rise to molecules of the same size (perhaps one eighth of the original value). Some experiments with hæmoglobin show that this protein too is dissociated in the presence of other proteins and clupein, but here the sedimentation constant indicates that the dissociation at first gives molecules of half the original size, independent of whether lactoglobulin or clupein is used.

As the effect seems to be of a more general nature (whether it is a dielectric or chemical effect or a combined effect is at present impossible to decide) it is to be expected that it may also take place in a more concentrated solution of a uniform protein, and these solutions should therefore give a decreased molecular weight with increasing protein concentration. This may at least partly explain the fact that several investigations show that the proteins are behaving osmotically abnormally in that the ratio π/c (π = osmotic pressure, c = concentration of protein) increases with increasing protein concentration, as it should do if the molecular weight is not constant, but decreases with increasing concentration.

Information about this effect may be of value in explaining some of the biological processes, where we are dealing with more or less concentrated protein solutions.

Further details will be given in a forthcoming paper in the *Biochemical Journal*.

Effect of Phenylacetic Acid on the Growth of Tomato Plants

MUCH interest has been taken in the action on the growth of plants of various organic substances which has been described by the workers at the Boyce Thompson Institute[1,2]. They apply these substances in lanolin preparations to plants, or as a water solution added to the soil or injected into the stem; the main responses of the treated plants being epinasty of the leaves, swellings and proliferations of the stems and petioles, and formation of roots on or near the treated part. In the course of some tests carried out at East Malling Research Station, using phenylacetic acid, I sprayed a batch of tomato plants with a 0·1 per cent solution in water, while control plants were sprayed with water containing a little alcohol. The solution was prepared as described by Hitchcock and Zimmerman[3]. By the spray method, the amount of growth substance applied can be fairly accurately controlled. Entry was very rapid; epinasty of the leaves being visible after one hour in a greenhouse at a temperature of about 20° C. The plants were treated in the morning, and by the next day the leaves had fully recovered; moreover, very little stem bending had occurred, showing that the distribution of the growth substance was uniform throughout the stem. The treatment was continued daily, and groups of plants were harvested weekly; the fresh and dry weights being determined. Fig. 1 shows a treated and a control plant at the end of two weeks.

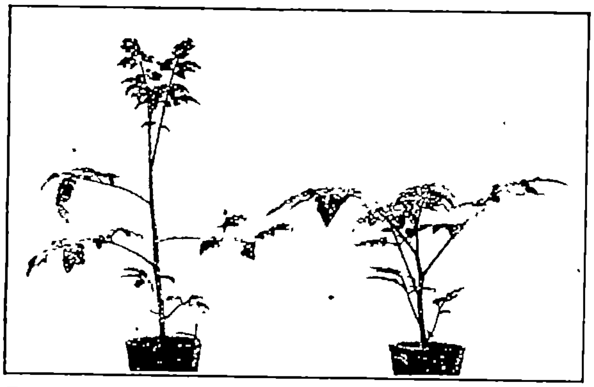

FIG. 1. The plant on the left has been sprayed daily for two weeks with 0·1 per cent phenylacetic acid Control on right sprayed with water.

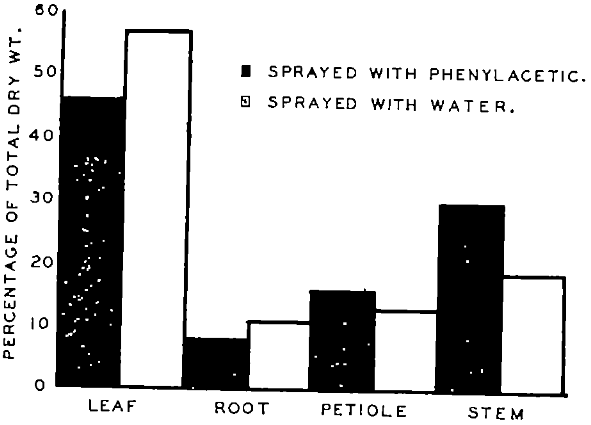

FIG. 2. Diagram showing the percentage of the dry weight present as stem, petiole, root and leaf after one week.

After one week the treated plants were more than thirty per cent taller than the controls, and the lengths of their petioles and internodes were also much greater. The diagram, Fig. 2, shows the percentage of the dry weight present as stem, petiole, root and leaf in the treated plants and the controls after one week.

From Fig. 2 it is seen that there are very significant alterations in the relative amounts of the various organs which make up the total dry weight of the plant. Thus the percentages of the total dry weight which are present as leaf and root have decreased, while the percentages present as stem and petiole have increased. These differences were maintained with little alteration after two and three weeks treatment. The water content of the treated plants had also increased indicating a more succulent type of growth. The total dry weight of the treated plants had not increased, however, and it would therefore appear that the growth substances may act not by increasing the growth of the plant as a whole, but by effecting the balance between stem, root and leaf.

If the treated plants were kept in a humid atmosphere, roots emerged from the stem after twelve to fourteen days. The spray method of applying the growth substance may therefore prove to be a convenient way of treating cuttings.

Structure of the Wall of *Valonia*

THE interesting röntgenographic studies of O. L. Sponsler[1] and of W. T. Astbury, T. C. Marwick and J. D. Bernal[2] on the cell-wall of the large one-celled alga of the genus *Valonia* have revived the interest in the older microscopic investigations by C. Correns[3] on the structure of the cell-walls of Algæ, including also *Valonia*.

Correns proved that the wall of *Valonia* and of some other Algæ consists of a large number of lamellæ, each containing numerous parallel cellulose fibrillæ, which are placed spirally around the axis of the cell, which is more or less of a cylindrical shape. The fibrillæ of the various odd-numbered lamellæ are practically parallel, as are those of the even-numbered lamellæ—there occur deviations of a few degrees—but the direction of the winding of the spiral in the odd lamellæ is opposite to that in the even lamellæ. In the case of *V. ventriculosa*, Astbury found that the angle made by the two directions may vary from 80° to 60°; for some *Cladophora* species this approaches 90°, according to Correns.

Up to now any explanation of the method by which this remarkable structure has been brought about is lacking.

H. J. Denham[4] has observed that the protoplasm stream in the cells of the pili on the stamens of *Tradescantia virginica* near the cell-wall often runs exactly parallel to the longitudinal or steeply spiral stripes of this wall. It follows from a remarkable study by P. Martens[5] that these stripes do not occur, as Denham thought, on the inner surface of the wall, but on the cuticula which covers the outer side of the wall; the inner side of the thin cellulose layer, situated under the cuticula, is completely smooth. By studying the double refraction of the cellulose layer, and by means of swelling experiments, I have been able to prove that the rod-shaped cellulose crystallites in this cellulose layer possess a 'statical preference' for the transverse direction. The layer has therefore a micellar structure which sometimes is called 'Röhrenstruktur'. The protoplasm courses approximately perpendicular to the direction which is most preferred by the crystallites in the cell-wall.

From a series of other important investigations of P. Martens[6,7] it follows that the markings on the cuticula very generally are indications of the tensions which occur therein by the active growth and the passive stretch of the cell-wall layer situated under the cuticula. The stripings on the cuticula of the pili of *Tradescantia* are really therefore the result of the fact that the cellulose layer lying underneath is most stretchable in the direction which is practically perpendicular to the one preferred by the crystallites. The relation referred to here between the direction of the greatest stretchability and the internal structure has been settled satisfactorily by R. Sonntag[8], P. Jaccard and A. Frey[9].

It may be assumed that the protoplasm lying directly against the inside of the cellulose layer, as a result of the stretching of that layer, is in a state of tension in the same sense as the cuticula, and that the protoplasm stream is *directed* by this tension along that layer. This explains the observation of Denham, which, through Martens' observations, had proved puzzling.

Various careful observations have been made by H. Crüger[10], L. Dippel[11] and E. Strasburger[12], from which it appears that the secondary thickenings which are often deposited on the inner side against the primary wall layer (not, however, in the case of the pili of *Tradescantia*, where the wall remains primary) are formed in the protoplasm streaming along the wall, and in such a way that it looks as if the protoplasm along the wall changes into wall substance. I directed attention in 1927[13] to the fact that the rod-shaped cellulose crystallites in such secondary thickenings are deposited in the direction of the protoplasm stream along the wall. The crystallites are probably arranged by the stream in the direction of the stream.

From the foregoing it will now be clear why, in numerous cell-walls, the direction of the crystallites in the secondary wall layer is more or less perpendicular to that in the primary layer. The direction of the crystallites in the secondary layer is hence determined by the direction of the greatest stretchability of the primary wall layer. In the case of a completely homogeneous wall structure the directions of the crystallites in the primary and in the secondary wall layer will therefore be *exactly* perpendicular to each other, but a priori deviations from this position may be expected.

The normal case appears to be that the secondary deposition begins after the stretchability of the primary wall has been greatly diminished, in such a way that after deposition has taken place, practically no stretch of the wall occurs. If one supposes, however, that after a secondary wall layer has been deposited the primary wall regains its stretchability by the intussusception of new cell-wall material, then the protoplasm near the wall will be subjected to a tension which is now perpendicular to the direction of the crystallites in the secondary layer. A tertiary layer will then be deposited, of which the crystallites are approximately perpendicular to those in the secondary. This process may repeat itself periodically, for example, by the strong passing increase each day of the turgor pressure in the cell, due to carbon dioxide assimilation in daylight. If one considers further that by the growing together of the rod-shaped cellulose crystallites placed next to, and end-on-end with each other, fibrillæ may be formed, then one may realize that the remarkable structure of the cell-walls of *Valonia* and other Algæ may be the result of the above mentioned process.

Applying the above train of thought, this structure should be effected by a periodic repetition of a process of wall thickening very generally found.

Insect Coloration and Natural Selection

IN NATURE of August 8 there appear two letters on the subject of natural selection: one from my friend, Prof. H. E. Armstrong, and another from my friend, Prof. Hale Carpenter. Prof. Armstrong in his attack on "Natural Selection" quotes me. Prof Carpenter in his reply thinks that Prof. Armstrong's objections are easily answered. At the risk of appearing tedious, I desire to make one more effort to bring home to Prof. Carpenter the insuperable objections which exist to the explanation of "mimicry" or any other biological phenomenon whatever from "natural selection".

By mimicry Prof. Carpenter means the theory that superficial resemblances between different groups of butterflies and similar resemblances between flies and beetles, etc., resemblances in colour or shape or attitude, have the function of enabling the weaker of the two to escape its enemies. Every part of an animal has some relation to its life, which is a constant reaction to its environment, but whether these resemblances really act in the way in which Prof. Carpenter supposes is an open question. Certainly one is not convinced by his *obiter dicta*. Each case requires a renewed and critical examination, which so far it has not received. I need only say that two of the most distinguished entomologists living, Dr. McAtee, of the U.S. Biological Survey, and Dr. B. P. Uvarov, who first elucidated the problem of the migratory locust, repudiate the "natural selection" explanation of mimicry. Worse than all is the statement by Bergh in his "Nomogenesis", that the only case on record of a species of butterfly being seriously decimated by birds is that of a Danaid—a supposedly distasteful species—in Ceylon.

Even if Prof. Carpenter were proved to be right, however, and these "mimicking" resemblances really did function in the way he supposes, "natural selection" would be incompetent to explain them. "Natural selection" in a sense is a truism; it merely asserts that an organism exists and maintains itself, which is sufficiently obvious. But what the theory covertly assumes is that random inheritable variations in all directions are constantly taking place by *chance*—and that is simply not true. All the experimental evidence obtained by testing this point has given the same answer, and it is surely unsafe to base any biological theory on an assumption which has proved to be false. But it may be answered that 'mutations' are inheritable. Mutations have now been artificially produced, and always by similar experiments. If the eggs or young embryos are exposed to noxious conditions, then a large number are killed; some survive and develop normally whilst there is a border group of what we may term the 'half-killed' which develop into mutations. All mutants compared with the type are defective in vigour and viability. Mohr, the great authority on *Drosophila*, has constructed a scale of mutations: the slight mutations produce a slight effect on viability, the more obvious ones a greater effect, the most obvious a semi-lethal effect. Moreover, if mutants can be restored to normal conditions, after a certain number of generations they revert to normal development, and the mutant appearance which Johannsen defined as a "superficial disturbance of the chromosomes" passes off. No mutation has ever given rise to a natural race.

We have definite evidence that insects, like other animals, react to changes in the environment by changes in growth and appearance, and that when these changes in the environment are long continued, their effects become so engrained in the constitution that they are in ever-increasing measure inherited by the offspring. This has been proved by Heslop Harrison for the egg-laying habits of *Pontania salicis*, by Durkheim for the coloration of Pierid pupæ, for feeding habits by Miss Sladden and, *mirabile dicta*, for the colour of the imago of butterflies by Weismann himself.

When fully documented evidence for evolution as displayed by a minute study of species and races of living forms or by the study of lineage series in fossils is carefully studied, this dependence of evolutionary change on change in habit and function becomes apparent. It is useless to demand miracles in the shape of supposedly beneficial mutations to explain changes where the full evidence is not at hand. When and if it is available, I am convinced that apparently inexplicable cases will yield to the same explanation of inherited habit as those cited above.

The External Forces Acting on Chromosomes

According to Darlington[1], in somatic mitosis or meiosis, "the equilibrium position reached at metaphase may . . . be described as the result of the combination of three kinds of repulsion acting on bodies in the confined space of the spindle", the repulsions being between chromosomes, between spindle attachments, and between poles and spindle attachments. If therefore at the first metaphase of meiosis there should exist two kinds of bivalents the different shapes or sizes of which cause the spindle attachments of the component chromosomes to be farther apart in one kind than in the other, we should expect the former type of bivalent to be pushed to the edge of the plate.

In the plant *Silene Otites* Wibel, the chiasmata at first metaphase are all terminal or nearly so, and a mixture of rod bivalents with one chiasma and ring bivalents with two chiasmata is found, the spindle attachments being farther apart in the rod bivalents. The latter tend regularly to be arranged on the edge of the plate, a minor, but none the less striking, verification of the theory.

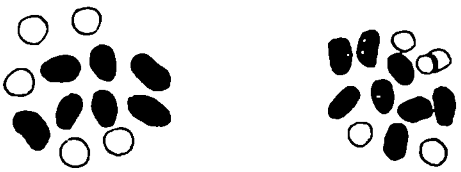

FIG. 1 Two polar views of the first metaphase of meiosis in pollen mother cells of *Silene Otites* Wibel For the purpose of illustration the bivalents with one chiasma are shown in outline. (×3000 approx.).

In the polar views represented in Fig. 1 the bivalents with one chiasma can be distinguished by their smaller and more circular cross-section. The illustrations represent an apparent contradiction of the general rule that the largest chromosomes are found on the outside of the metaphase plate, but actually, as can be seen more clearly in side views, the difference is one of shape rather than of size.

[1] C D. Darlington, "Recent Advances in Cytology". J. & A. Churchill, London, 1932.

The different distribution of rod and ring bivalents found by Mr. Fyfe in *Silene* is a clear and hitherto unnoticed example of the principle of repulsion-equilibrium in the formation of the metaphase plate. This effect evidently depends on the numbers of chromosomes, on the equality of their sizes combined with the variation in the number of their chiasmata, and on a certain size-relationship of chromosomes and spindle. Less conclusive evidence of the same distribution is to be found in my figures of *Primula sinensis*[1], *Campanula persicifolia* and diploid *Tradescantia*. In the last case the body-repulsions assist in producing the differential effect. Where the chromosomes are more numerous, as in *Aesculus*[2], the differential distribution is not clear without statistical treatment.

The detailed study of the congression and distribution of the bivalents on the plate in relation to their size and chiasma structure makes it possible now to describe the forces at work with more precision than a few years ago, especially in showing that the repulsions are an inverse function of distance[3].

Provisional Computation of the Plane Vibration Frequencies of Symmetrical Deuteroethylenes

SEVERAL workers[1,2] have developed the theory of the vibration spectrum of ethylene and have deduced from the experimental data values for some of the force constants occurring in the potential energy function of the molecule. A recent investigation by Bonner[3] has improved our knowledge of the vibration spectrum of ethylene.

The most general potential function for plane deformations which is compatible with the admitted symmetry of that molecule contains 15 constants. On the other hand, as there are 9 plane normal modes, it seems at first that only 9 constants of force can be determined from the present data. However, in order to reach a precision in accord with the accuracy of some data (1 cm.$^{-1}$), 11 constants are necessary, owing to reality conditions to be satisfied. Such a numerical potential function has been calculated for ethylene from Bonner's experimental data and checked by recomputation of the vibration frequencies with less than 0·15 per cent error.

Assuming that the potential function is not altered when 'heavy' hydrogens are present in the molecule, the vibration spectrum of C_2D_4 was readily obtained. The spectrum of each of the three isomers $C_2D_2H_2$ was calculated from two secular equations, one of the fifth degree, the other of the fourth. Each of them results from coupling together two families of normal modes of different symmetries in the completely symmetrical molecule C_2X_4, in such a way that a mode of the isomer of lower symmetry is produced. The coupling occurs through the kinetic energy function only, which has a lesser symmetry for the isomeres than for C_2X_4.

	C_2H_4	C_2D_4	HDC : CDH *cis*	HDC : CDH *trans*	$H_2C . CD_2$
1	S_1 1621 8	S_1 1428 8	π' 1516 5	S 1514 2	π 1555 3
2	3019 0	2283·9	3065 0	3049·2	3004 3
3	1343 9	1008 9	2304 2	2291·2	2221 0
4	A_1 2988 0	A_1 2152 5	1247·9	1240 2	1357 8
5	1444 0	1072·8	752 7	807·9	1043 1
6	S_2 3069 0	S_2 2308 0	σ' 3031·1	A 3053 2	σ 3088·1
7	950 0	758 3	2228·9	2233 4	2316 3
8	A_2 3107·0	A_2 2325·0	1295 4	1308 4	945·6
9	949·7	678 1	820 2	765 3	724 8

The horizontal lines separate the frequencies in different symmetry families. S and A, respectively, mean symmetric and antisymmetric with respect to the centre of the molecule. S frequencies are Raman active and infra-red inactive; the reverse is true for A frequencies. π and σ respectively mean symmetric and antisymmetric with respect to the carbon axis and π' and σ' the same with respect to the perpendicular axis in the plane of the molecule. They are all active in Raman effect and in infra-red absorption, but may be of widely different intensities. The π and π' frequencies are polarized and expected strong Raman lines, whereas the σ and σ' are depolarized and weaker. As is well known, for C_2H_4 and C_2D_4, S frequencies divide into two separate families $S_1(\pi\,\pi')$ and $S_2(\sigma\,\sigma')$ and also $A_1(\pi\,\sigma')$ and $A_2(\pi'\,\sigma)$. The π frequencies show a marked Q branch in the infra-red absorption. The four fundamental symmetry families of the totally symmetric molecule combine in the following way to form the normal modes of the three isomers: $\pi'(S_1A_2)$; $\sigma'(S_2A_1)$; $\pi(S_1A_1)$; $\sigma(S_2A_2)$; $S(S_1S_2)$; $A(A_1A_2)$.

Owing to the uncertainty resting upon some data and also the neglect of the anharmonicity, no too close fit with the experiment can be hoped. However, it is expected that the obvious qualitative relationships existing between the spectra of heavy ethylenes will hold.

Some Properties of Pentadeuterobenzoic Acid, C_6D_5COOH

THE acid was obtained by the reaction between pentadeuterophenyl magnesium bromide and carbon dioxide[1]. The following details enable a comparison to be made between this acid and benzoic acid:

	C_6H_5COOH	C_6D_5COOH
Melting point .	121·7° C.	120·9° C.
Solubility in 100 c.c. water at 18° C :	0·28 gm.	0·34 gm.
Molecular heat of combustion :	771400 cal.	761880 cal.
Dissociation constant at 25° C :	$6·6 \times 10^{-5}$	$6·6 \times 10^{-5}$

A detailed account of this work will shortly appear in *Helvetica Chimica Acta*.

Nuclear Reactions due to Neutrons of 2 m.e.v. Energy

MOST neutron workers hitherto have used Ra-Be, Ra-B or Ra-F as sources; these yield neutrons with continuous ranges of energies extending up to several m.e.v. The D – D nuclear reaction is considered to yield a homogeneous group of neutrons of about 2 m.e.v. energy. It is of interest, therefore, to know whether or not D – D neutrons can excite the nuclear reactions of the non-capture type reported by investigators using the radioactive sources.

We have been working in the Clarendon Laboratory with the neutrons obtained by bombarding heavy hydrogen with heavy hydrogen ions. The source of ions was a low-voltage arc of a modified Tuve and Dahl type. The total ion currents used have been of the order of 100 microamps. The accelerating voltage was 225 kv. Heavy phosphoric acid has proved to possess reasonably good lasting qualities as a target material. The yield of neutrons, as measured by the 2·3 min. induced activity of silver, has been checked at intervals over fifty hours' intermittent use, and has shown a constancy well within 10 per cent. Continuous runs of up to six hours' duration have been made.

With the exceptions of silicon and iron, the element under investigation was itself exposed to the 2 m.e.v. neutrons and then tested for induced radioactivity by means of a thin-walled Geiger-Muller counter. Silicon and iron were irradiated as SiO_2 and FeS respectively.

Silicon and phosphorus (half-periods, 2·5 min.) and phosphorus (half-period, 2·5 hr.) have been reported upon by Bjerge and Westcott[1]. They found a measurable activity only in the case of the 2·5 hr. period of phosphorus.

We have bombarded the following elements with our 2 m.e.v. neutrons for times up to twenty minutes in order to test for the shorter period activities: manganese and chromium (half-period, 3·75 min.), aluminium (10 min.), zinc (5 min.), silicon (2·3 min.). Any activity induced was certainly less than 1 per cent of the activity-value for phosphorus (2·5 hr.) irradiated to saturation under the same conditions.

Exposures for times up to three hours were carried out on zinc (half-period, 6 hr.), iron (2·5 hr.) and nickel (20 min.). No activities were found greater than 2 per cent of the saturation phosphorus value.

Calcium (16 hr.), magnesium and aluminium (15 hr.) were irradiated for periods up to six hours. Here again, our counter showed no activity as high as 2 per cent of that of phosphorus.

Naturally, any of these reactions might yield a positive result with a stronger source of neutrons or, in the case of the long-period ones, with a longer period of irradiation. We are making alterations which should greatly increase the number of neutrons available. Further investigations will be made on the above and other elements.

Ultra-Violet Absorption Spectrum of Hæmoglobin

IN a previous communication (Adams[1] *et al.*, 1934) it was shown that the ultra-violet band at 4100 A., which is characteristic of hæmoglobin and its immediate derivatives, is not found in unlaked blood. This observation has been extended to several species and confirmed in all cases.

It has been found that the difference in physical state is not responsible for the absence of the band when the hæmoglobin is in the corpuscle. The cell volume was varied by placing the cells in solutions of different osmotic strength, but not more than 5 per cent variation in light absorption was observed. Precipitation of the hæmoglobin with a protective colloid gave a suspension of hæmoglobin with a density about equal to that of a blood corpuscle suspension. This preparation, although similar in physical properties to a cell suspension, displayed the same ultra-violet absorption spectrum as hæmoglobin in solution.

The explanation for the non-appearance of the band in the corpuscle was next sought in the possible combination of hæmoglobin with some constituent of the red blood cell to give a compound with no specific absorption at 4100 A. Attempts to combine cholesterol, lecithin, glutathione and lipid extracts of the cells with hæmoglobin did not yield substances which lacked the band at 4100 A. 'Stromatin', or stroma protein, was prepared by Jorpes' method[2] (1932). The pure protein does not exhibit any selective absorption in the 4000 A. region. However, if a small percentage of hæmoglobin or methæmoglobin remained as an impurity in the preparation, the hæmoglobin band was absent.

This suggested a combination between hæmoglobin and stromatin to give a substance with no absorption at 4000 A. A small amount of pure stromatin was mixed with dilute hæmoglobin in alkaline solution. The spectrogram was taken at once, and at regular intervals for several hours afterwards. The mixture was kept at 37° C. The results show that, after heating at this temperature for 30 minutes, the ultra-violet band of hæmoglobin began to disappear, and at the end of one and a half hours there was no trace of selective absorption at 4100 A. The experiment was controlled by treating hæmoglobin with the same amount of alkali in a similar way.

The results of these experiments lead to the conclusion that neither the crude lipids of the red blood cell, cholesterol, lecithin, or glutathione react with hæmoglobin in such a way as to change the specific absorption of hæmoglobin in the region of 4100–4200 A. On the other hand, pure stromatin does react with hæmoglobin to cause the disappearance of its specific band at 4100–4200 A.; and it is suggested that this same combination exists in the red blood cell, and is responsible for the lack of the specific absorption band in corpuscle hæmoglobin. Such an entity is apparently quite labile, since hæmolysis by a wide variety of agents causes the breakdown of the substance.

Potassium in the Brain in Vitamin B_1 Deficiency

IT has been stated that there is increased amount of potassium in the brains of pigeons suffering from vitamin B_1 deficiency. In view of the general interest attached to potassium salts and phenomena of excitation, I have re-examined this question. Unfortunately, I cannot find any significant difference between the amounts of potassium in the brains of normal and vitamin B_1 deficient pigeons, the values being 3·6 mgm. per gram of tissue in each case. The changes obtained by these authors[1] cannot, therefore, have been due to the avitaminosis.

Kinetics of an Inverse Diene Synthesis in the Pure Liquid State

THE decomposition of di*cyclo*pentadiene into *cyclo*pentadiene is an inverse diene synthesis. It was found previously[1] that in paraffin solution the reaction is monomolecular and that the rate constant is given by $k = 6 \cdot 0 \times 10^{12} e^{-34000/T}$ sec.$^{-1}$.

The rate of the decomposition has now been measured in the pure liquid state, using a method by which the *cyclo*pentadiene was continuously removed from the reaction mixture. Measurements have been carried out between 100° and 155°, and within this range the Arrhenius equation is obeyed. The value of the rate constant is $k = 3 \times 10^{13} e^{-35400/RT}$ sec.$^{-1}$, and the close agreement with the above figure shows that the mechanism of the inverse diene synthesis is the same both in solution and in the pure liquid state.

London.

---

[1] NATURE, 137, 496 (1936).

THE formation of di*cyclo*pentadiene from *cyclo*pentadiene is a diene synthesis and the reaction is bimolecular in benzene[1] and in paraffin solution.

If rate measurements in the pure liquid state are carried out it has to be considered that the 'solvent' originally present (*cyclo*pentadiene) is changed into a new solvent (mixture of *cyclo*pentadiene and di*cyclo*pentadiene). Hence it is not surprising that in each run a gradual change of the bimolecular rate constant (k) is observed. The constants characteristic of pure *cyclo*pentadiene are obtained if the observed k values are extrapolated to zero time. Both the extrapolated constants and those observed in benzene or paraffin solution obey the Arrhenius equation. The 'temperature independent factors' (Z) and the activation energies (E) are given in the accompanying table.

Reactants	Solvent	Z^1/gm.mol.sec. $\times 10^{-6}$	E kgm.cal.
*cyclo*Pentadiene	Benzene	1·2	16·4
*cyclo*Pentadiene	Paraffin	13	17·4
*cyclo*Pentadiene	*cyclo*Pentadiene	0·4[2]	16·1[2]

The accuracy of E is 5–10 per cent. It can be seen that the E's agree within the limits of experimental error. Further, the Z values and hence the collision numbers between solute-solute molecules and between solute-solvent molecules are of the same order of magnitude.

ALBERT WASSERMANN.

University College,
London.

[1] NATURE, loc. cit.; *J. Chem. Soc.*, 1028 (1936).

[2] These values were calculated using unpublished measurements and the data given by Stobbe and Reuss, *Annalen*, 391, 151 (1901), Barret and Burrage, *J. Phys. Chem.*, 37, 1029 (1933) and Kistiakowsky and Mears, *J. Amer. Chem. Soc.*, 58, 1060 (1936).

Points from Foregoing Letters

THE use of contoured graphs for determining the configuration of atoms in crystals, from X-ray data, is explained and illustrated diagrammatically by Prof. W. L. Bragg. The analysis of atomic positions, it is claimed, can be more rapidly carried out with the graphs than by calculation.

The addition to serumalbumin solution of a protein (clupein) changes the sedimentation constant. The effect, according to Dr. K. O. Pedersen, is probably due to dissociation into molecules of perhaps one eighth the original size. This, the author considers, may be a general phenomenon which occurs with increasing concentration, even in solutions of a single protein, and may account for the abnormal increase in osmotic pressure with increased concentration of protein solutions.

A method of applying organic growth substances to plants by spraying is described by Dr. H. L. Pearse. Tomato plants sprayed with a dilute solution of phenylacetic acid showed increased growth in stem and petiole, with decreased growth in leaf and root.

Algæ of the genus *Valonia* form very large bladder-shaped cells. By X-ray, microscopical and optical investigation of the wall, it may be shown that sub-microscopical rod-shaped cellulose crystals (crystallites) are present. The wall consists of about forty lamellæ; in the odd-numbered lamellæ all rods are parallel to each other, and in the even ones also, but in a direction which forms a large angle with the direction of the crystallites in the odd lamellæ. Prof. G. van Iterson, jun., gives an explanation of the way in which this structure is developed.

In connexion with the discussion on the origin of mimicry in insects, Prof. E. W. MacBride disagrees with the view that random inheritable variations in all directions constantly take place by chance. He considers that animals react to changes in environment and, when these are long continued, their effects are increasingly inherited by the offspring.

Diagrams showing the position of chromosomes during the metaphase stage of the reduction division (meiosis) in pollen mother-cells of *Silene Otites* are submitted by J. L. Fyfe; they agree with the view of Dr. C. D. Darlington, that the configuration is determined by repulsion forces. Commenting on this communication, Dr. Darlington refers to additional evidence in support of his theory and states that the repulsions are inversely proportional to the distance.

A table giving the vibration spectra of several ethylenes containing heavy hydrogen (C_2D_4 and each of the three isomers $C_2D_2H_2$) is given by Prof. C. Manneback and A. Verleysen. The values were calculated from the known vibration spectrum of ordinary ethylene, by assuming that the 'potential function' is not altered when heavy hydrogens are present in the molecule.

The melting point, solubility, heat of combustion and dissociation constant of benzoic acid containing five heavy hydrogen atoms in the molecule are reported by Prof. H. Erlenmeyer and A. Epprecht.

No appreciable radioactivity has been observed by E. T. Booth and C. Hurst after irradiating, for periods varying from twenty minutes to six hours, substances containing various elements with neutrons of two million electron volts energy; these were obtained by bombarding heavy hydrogen with heavy hydrogen ions, using total ionic currents of 100 microamp. and an accelerating voltage of 225 kv.

Hæmoglobin as found in blood corpuscles differs from the prepared 'laked' variety in that it does not show an absorption band in the ultra-violet at 4100 A. G. A. Adams, after investigating the effect of several substances, finds that the addition of stroma protein (stromatin) causes hæmoglobin to lose its absorption band at 4100 A., and concludes that hæmoglobin occurs in blood in combination with stromatin.

Research Items

Marriage among Serbian Gypsies

IN continuation of his studies of the Serbian gypsies, Dr. Alexander Petrović deals with marriage (*J. Gypsy Lore Soc.*, Ser. 3, 15, 3), drawing his material from Belgrade, Kragujevač and the neighbourhood of Arandjelovač, Rogatica, and Srebrnica. The gypsies from the two latter are Mahommedans, the remainder Orthodox. The marriage age is—Orthodox, boys, 13–18, girls, 12–16; Mahommedan, boys, 15–20, girls, 14–16. The later age among the Mahommedans is due to their custom of purchase, which involves a large sum. Neither bachelors nor old maids exist among the Christians, and to remain unwed is a disgrace. In olden times, marriages were celebrated at a much earlier age. The older generation used to betroth their children at 7–10 years and sometimes even before birth. In marriages in which the groom is very young, the bride usually being older by many years, it is customary for the father, or even grandfather, to be intimate with the bride in order to prevent her running away. These marriages secured a life-long bread-winner for the husband. Another reason given for early marriage is to ensure the descent in the male line and inheritance of the 'Slava' (patron saint) with the duty of celebrating his feast, as well as of burning candles in church for the parents after their death. The marriage is arranged by the father of the boy or the oldest man in the family. It is characteristic that when once a gypsy has decided on marriage, there is no delay. In marriage rites there is a tendency to imitate the customs of the neighbouring villages. Among some of the distinctive gypsy customs recorded is the pricking of a willow tree three times with a knife; while one of the chief marriage customs of all Serbian gypsies, but now no longer observed, was marriage around a tree. Even now, at Srebrnica, ties of marriage celebrated around a willow tree are considered more sacred than those celebrated by the 'Kadija'. In Mirijevo, the willow "symbolizes the woman". The rite of exposing evidence of virginity is widespread, as strict views are held on the subject of the virginity of the bride.

Tattooing in China

PROF. CHUNGSHEE H. LIU has initiated a historical survey of tattooing in China by a study of the practice as it still exists among the aboriginal Li people of the island of Hainan, southern China, which he contributes to the newly founded *Journal of Science*, published by the Sun Yatsen Institute for the Advancement of Culture and Education, Nanking. Tattooing is recorded under the Shang and Chou dynasties, when it was practised to avoid the trouble of dragons and snakes. No evidence for the custom can be traced among the 'Southern Barbarians' of the Middle Kingdom, where it might be expected. Among the Li, where it is called 'tatan' (cf. Polynesian 'tatu'), there are two traditions of its origin. According to one, it was a tradition of their ancestors that they might recognize their descendants easily; according to the other, when a mother and son were the only survivors of a great deluge, the former disguised herself by it from her son's recognition at God's bidding in order that the earth might be repeopled. Tattooing is practised only by the women. The instruments used are a rattan needle and bamboo rod, with black ash, or Chinese ink. The designs are first drawn. The technique is not of a high standard, and is known to most old women. The designs may be divided into four groups: (1) oblique lines in twenty-seven forms, mostly used on the face; (2) horizontal lines in seventeen forms, mostly on the legs, but partly on the arms; (3) circular lines, twenty-five forms, mostly on the chin; and (4) linguistic forms, recorded only among the Pai-sha Li, and unintelligible. The practice may be interpreted as a system of tribal marking, as related to marriage, or the totemic idea, as a magic symbol, or as purely decorative. The custom is dying out, and should be studied further before complete extinction.

Respiratory Dust Disease in the Cotton Industry

COTTON spinners do not suffer more than operatives in many other dusty occupations from respiratory tuberculosis, bronchitis and pneumonia; but cotton 'strippers' suffer a bronchitis mortality more than double that in other dusty trades. These operatives remove the dust from the carding machines, which comb out the cotton fibres, producing much dust in the process. The cause of this excessive mortality from bronchitis among these hands has been investigated by Prof. Carl Prausnitz (formerly of Breslau) in Prof. Maitland's Department at the University of Manchester, and his conclusions are published in a Report to the Medical Research Council (Special Rep. Series, No. 212. London: H.M. Stationery Office, 1936. 2*s*. 6*d*. net). Chemical examination showed that three fractions may be extracted from the dust, a lipoid or waxy fraction with petroleum ether, histamine with alcohol, and protein with saline solution. The lipoid is apparently quite harmless, the histamine has also a doubtful role as a disease-producing agent, but the protein is definitely toxic, causing irritant effects and inflammatory lesions in the deeper tissues. It also causes a condition of allergic hyper-sensitiveness; this was demonstrated by animal experiments, and was found to be present in all diseased cotton operatives examined. Various treatments for mitigating the disease are suggested, but the leading principle consists in prevention. This may necessitate the provision and use of adequate respirators, for even powerful and properly directed ventilation fails to carry away the lightest and smallest particles of dust.

Seals in Cornwall

COMPLAINTS by fishermen in Cornwall regarding the damage caused to fisheries of mullet and herring by seals have led to a careful survey of the seal population by G. A. Steven (*J. Mar. Biol. Assoc.*, 20, 493; 1936). The only seal observed by him on the Cornish coasts was the grey seal, *Halichoerus grypus*, and its habit was to frequent, during the rest of the year as well as during the breeding season, caves which were inaccessible from the land side. During the survey (August 7–20, 1935) the numbers counted indicate a seal population on the north coast of not less than 300 and probably not more than 500; on the south coast the number, not estimated, is very small. This differs very markedly from the estimate of 2,000 adhered to by the Cornwall Sea Fisheries Committee, and seems a much more trustworthy basis upon which to discuss any steps contemplated for the reduction of the seal population in the interests of the fishermen.

Larval Transplantation in Axolotl

KOLODZIEJSKI (*Bull. Internat. Acad. Polonaise*, Feb. 1936) reports the results of implanting axolotl larvæ upon hatching or within the first week or so in axolotls eight months old; all the implants were the offspring of the same parents. The skin of the back of the larvæ was cut, and they were inserted into holes in the dorsal fin of the host so that the tissues of the two animals could grow together. In some experiments the host skin grew over the implants, in others the implant fell off, but the majority fused successfully. The growth of the implants was fairly rapid at first, slowed down at four months and ceased altogether at six months, although some were kept alive for fifteen months. The internal organs of the implants developed more or less normally, but the external parts exhibited a wide range of abnormalities. Generally the body and tail were much reduced and the hind limbs entirely absent, while the fore limbs were often present and normally developed, and the head in some developed for several months. The reflexes and motility of the implant were independent of those of the host and were more developed where the body form more nearly approached the normal. Many implants had well-developed testes with motile spermatozoa, and while this condition was more common in those on male hosts it also occurred in those on female hosts. The lips of the cloaca were usually wide open, and in implants on male hosts the cloacal lips were markedly developed independently of the stage of maturity of their own gonads.

Morphology and Distribution of Penæids

MR. MARTIN D. BURKENROAD now concludes his preliminary review of the Penæidæ begun in two papers dealing chiefly with the littoral members of the family (1934 *a* and *b*) ("The Aristaeinae, Solenocerinae and Pelagic Penaeinae of the Bingham Oceanic Collection. Material for a Revision of the Oceanic Penaeidae". *Bull. Bingham Oceanographic Coll.*, Peabody Museum of Natural History, Yale University, 5, 1936). The members of these subfamilies are largely oceanic and of great interest in structure, habits and distribution. The question as to the relation between structural characters of penæids and their bathymetric habits is discussed and the distributional relations between the oceanic penæid faunas of the Atlantic and Pacific American regions. The larger part of the monograph of 151 pages is morphological, and the species are described and compared in great detail. The *Pawnee* third expedition collected a large number of species, four of which are new, but the descriptions are not confined to these, for there is also material from three co-operative cruises of the research ship *Atlantis*, sponsored jointly by Woods Hole Oceanographic Institution and by Yale University (Bingham Oceanographic Laboratory), and many more species are brought into the discussion dealing with the affinities of the various genera. Useful synopses of their main characters are given. All this very careful work is an important addition to our knowledge of this group of decapod crustaceans.

New Work on Cœlenterates

PROF. OSKAR CARLGREN has described a very interesting new Lucernariid from South Africa ("Ueber eine neue sudafrikanische Lucernariide., *Depastromorpha africana* n.gen. n.sp., nebst bemerkungen uber den bau und die systematik dieser tiergruppe". *Kungl. Svenska Vetenskapsakademiens Handlingar*, Tredje Serien. 15, No. 1; 1935). Besides the detailed anatomical description of *Depastromorpha*, the author has added a comparison of all known genera belonging to the Lucernariidæ with special reference to the musculature, and a table showing the relationships. This cœlenterate family occurs chiefly in northern and southern parts of the world, especially in the Arctic and Antarctic. Until 1933, only antarctic and sub-antarctic forms were known in the southern part of the Atlantic and Indian Oceans. In 1933, Dr. Carlgren described a *Lipkea* from the coast of South Africa, and in 1935 Prof. T. A. Stephenson discovered in Kapstadt the species which is the subject of the above paper. Mrs. L. M. I. Macfadyen (Miss L. M. I. Dean) has described the Stolonifera, Alcyonacea, Telestacea and Gorgonacea of the Great Barrier Reef Expedition 1928–29 (Scientific Reports, 5, No. 2, British Museum (Natural History), 1936). The collection is a fine one, 51 species being described, of which 6 are new. The order Stolonifera includes several genera whose systematic position has caused discussion. Although agreeing with Prof. Hickson as to most of these, the author is of the opinion that *Solenopodium*, placed by him in the Stolonifera, is really a Gorgonacean. The reasons given are that it appears to be impossible to separate *Briareum* from *Solenopodium* as the spiculation is almost indistinguishable, and *Solenopodium* approaches towards the *Briareum* type of growth. It does not always show a creeping form of growth, but hollow stems grow upwards which are sometimes solid at the tops, forming as it were the beginning of a solid axis.

Brittle Stars from Puerto Rica

MR. H. CLARK has described four new species of brittle stars from the Puerto Rican Deep out of the collections made by the First Johnson-Smithsonian Deep-Sea Expedition (*Smithson. Misc. Coll.*, 91, No. 24. Johnson Fund. 1936). Among the numerous species obtained there are three new species of the genus *Ophiomusium*, two of which are interesting in having the upper of the two arm spines transformed into a hook curving outwards from the arm. There are eighteen specimens of *Ophiomusium regulare* n.sp., but only one each of the other two, *O. rosaceum* n.sp. and *O. alecto* n.sp. There is also a new species of *Ophiocira*, a genus of the family Ophiolucidæ, known heretofore only from the Philippine and Lesser Sunda Islands, from 220 fathoms.

Molluscs and Blood Flukes

ONE of the most widespread of the blood flukes infesting man is *Schistosoma japonicum*. Millions of the inhabitants of China, large numbers in Japan and smaller numbers in Formosa and the Philippines suffer from it. The intermediate host of this, as of many flukes, is a fresh-water mollusc. In spite of the considerable amount of work on the parasite and its relation to the primary host, little has been done on the intermediate host. Bartsch (*Smithsonian Miscell. Coll.*, 95, No. 5; 1936) has performed a useful piece of work by reviewing very fully the known molluscan hosts. A number of them is fully described, and they are shown to belong to at least four distinct genera. A series of good keys is provided, which should be of assistance to future workers.

Self-Sterility in *Eruca sativa* Mill

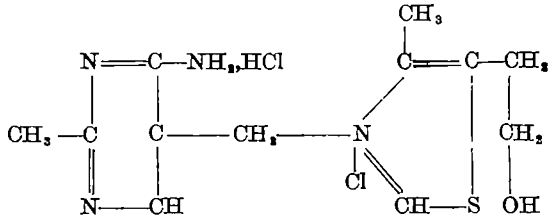
THIS crop plant of the Punjab is highly self-sterile and is normally cross-pollinated by insect visits to the recently opened flowers. Mr. Z. Alam (*J. Genetics*, **32**, No. 2) has made a genetical investigation of the self-sterility. Selfing reduces the length of pods by about one-third and the number of seeds to 2–3 per cent of that obtained from crossing. Plants raised from selfed seeds are weakly, shorter with fewer branches and pods, and give a lower yield of seed. Six plants were intercrossed in all possible ways. The results showed the existence of partially self-fertile as well as self-sterile plants. Some cross-matings were fairly sterile, and some compatible matings gave a much higher fertility than others. From bud pollinations it is concluded that a substance inhibiting pollen-tube growth is present in the style at anthesis, but is absent two days before and has gradually disappeared about two days after anthesis. Parthenocarpy and phenospermy were also observed in these experiments. The cause of different degrees of cross-fertility requires further investigation.

A Reagent for Structure Determination

IN the identification of organic compounds, those tests are especially valuable which can be carried out quickly on small amounts of material and show, by the formation of a colour or precipitate, the presence of a specific group or structure. R. Connor and J. H. Van Campen (*J. Amer. Chem. Soc.*, **58**, 1131 ; 1936) describe a test which, under specified conditions, is general for substances which contain hydrogen on a carbon atom bearing at least one acyl group or two other activating groups. The test consists in adding an alcoholic solution of mercuric chloride to a solution of the unknown in alcohol containing sodium ethoxide. The formation of a white (occasionally cream coloured) precipitate is a positive test. The negative test is the formation of a deep yellow precipitate similar to that obtained when the sodium ethoxide and mercuric chloride solutions are mixed in the absence of an additional reactant. More than two hundred organic compounds have been tested with the reagent, and it appears that it is desirable to limit its use to neutral compounds which do not contain elements other than carbon, hydrogen and oxygen. The classes of compounds with which the test will be concerned will include ketones, aldehydes, esters, hydrocarbons, ethers, acetals, alcohols, quinones and anhydrides. Of these, the last five types fail to give a positive test. Aldehydes and ketones with hydrogen on the carbon atom bearing the carbonyl group give a positive test. The only esters which give a positive test are those which have both hydrogen and a labilizing group on the carbon atom bearing the carboxyl group. Acetylenes appear to give a positive test, and are the only hydrocarbons to do so.

Synthesis of Vitamin B_1

IN June last (*J. Amer. Chem. Soc.*, **58**, 1063 ; 1936), Prof. Williams, of Columbia University, proposed a revised formula for vitamin B_1, in which 2.5-diethyl-6-aminopyrimidine is linked through the 5-methyl group to the nitrogen atom of 4-methyl-5-β-hydroxyethyltriazole. According to this view, the vitamin is the hydrochloride of a quaternary nitrogen base :



The Columbia University workers have now, according to a more recent communication from Prof. Williams to the same journal (loc. cit., **58**, 1504 ; 1936), isolated both the bromide and the chloride of a substance having the above formula, and have proved its chemical and physiological identity with the natural compound. The difficulties of their task may be imagined from the fact that the pyrimidine derivative was prepared by five stages from ethyl formate, acetamidine, $NH_2.C(CH_3):NH$, and γ-ethoxyethylacetate, $C_2H_5OCH_2.CH_2.COOC_2H_5$. This was then combined with the substituted thiazole, and the resultant bromide as well as the chloride prepared from it were compared with the corresponding substances from yeast. The thiazole compound appears to be prepared by six stages from ethyl aceto-acetate, β-bromethyl ether and thioformamide. Prof. Williams promises fuller details in forthcoming publications.

Dayload Peaks in Electrical Engineering Supply

IN the early days of electricity supply, it was soon realized that the machinery that had to be provided depended on the maximum (peak) load of the station. The higher the peak for a given load, the higher the price that had to be charged to the consumer. When direct current was used it was the custom to have a large battery of accumulators, which at times of light load were charged by the dynamos, and when the heavy load came they helped the dynamos by taking part of the load. Thus the load was equalized throughout the day. With alternating current supply it is more difficult to provide reserved power. In an article on "Dayload Peaks" published in the *Electrical Times* of August 13, it is stated that the time at which the peak load occurs is now in the process of changing from the evening to the morning. This is causing anxiety to those supply engineers who take a bulk supply, as their previous estimates will be upset and difficulties may arise. The following factors govern the times and nature of the daily peak load. One factor varies with the class of the load, which depends on the district, another on the time of the year, and a third on the weather. It has been noticed, for example, that the peak load occurs on a certain day at 5 p.m. A few days later, the weather being cold and foggy, it occurs at 9 a.m. This was due to the heating load from fires together with extra shop and domestic lighting. Except in large cities, there seems during the last two or three years to be a definite tendency for the maximum load to occur at breakfast time. If electric water heaters are used, and there is a large demand for hot water before breakfast, this in itself would be sufficient to cause a morning peak on the station load.

Twenty-five Years of Botanical Progress

THE Brooklyn Botanic Garden had the felicitous idea of marking the twenty-fifth anniversary of its foundation in part by the presentation and subsequent publication of a series of addresses dealing with progress in this period of time in different fields of botanical science. The series of addresses appears in vol. 4 of the *Memoirs* of the Garden (May 7, 1936), and will interest botanical readers everywhere.

The addresses were commendably brief, with the result that the most significant aspects in each field are usually thrown into prominent relief. Thus, Prof. C. E. Allen, dealing with cytology, after a brief reference to cytoplasmic structures, centrosomes and cell-wall, has a very penetrating analysis of the chief features of interest in chromosome studies in the twenty-five year period.

This pairs very well with Dr. Blakeslee's equally interesting review of the progress of genetics. Dr. Blakeslee finds that he is provided with about 0·7 seconds in which to discuss the twenty-five years work of each single geneticist, which produces the surmise that the so-called 'leaders of science' are rather 'pushed' than leading. "It is not the conspicuous spray which erodes the coastline of our continent but masses of water which surge forward with united front". Dr. Blakeslee regards us as passing, in 1910, from the Mendelism and 3 : 1 ratio period to that of "Brass Tacks—Genes and Chromosomes". The significance of three techniques are emphasized in this latter period; the aceto-carmine method which has enabled the rapid study of the nuclei of large numbers of specimens, the production of mutation by radiation treatment and the analysis of chromosomal structure permitted by the salivary glands of fly larvæ.

Dr. Blakeslee decides that the last twenty-five years have brought us again to the species problem, and appropriately enough a contribution follows by Dr. Elmer D. Merrill, director of the New York Botanical Garden, who deals most temperately and justly with the species problem as seen by the experienced taxonomist.

Many other points of view are discussed in this entertaining volume; virus diseases are passed in review, the progress of ecological investigation, of forest administration and research, etc. In short, it is made clear that in the last twenty-five years progress in botany has passed beyond the grasp of any one individual. Let us hope that the result will be to make us all as reasonable in our demands as specialists as Dr. Merrill, who concludes that it is neither necessary nor desirable that all botanists should master the field of systematic botany. "Yet it can be maintained as a general truth that the individual investigator, no matter what his field, who has a reasonable knowledge of the names and relationships of the organisms with which he deals, is a better equipped individual for productive work within his own field, and that the teacher of botany who has the same knowledge is a better teacher".

Geology in Great Britain

PART 1 of the "Summary of Progress of the Geological Survey of Great Britain" for 1933[1] contains the usual annual reports of the Geological Survey Board and of the director and gives particulars of routine work carried out during the year under review. As in the succeeding year, there was some slowing down of normal activities on account of the immense amount of additional work involved in preparation for the transfer of the collections to the new museum at South Kensington. Nevertheless, thirty-nine maps were issued, together with five memoirs, which, with one exception, have already been noticed in our columns (NATURE, 134, 782; 1934); the remaining one, the Merthyr Tydfil memoir[7], is reviewed below.

The old Museum of Practical Geology in Jermyn Street closed its doors to the public at the end of 1933. Sir John Flett contributes an interesting outline of its history from its opening in the year of the Great Exhibition of 1851 (see also NATURE, 134, 129; 1934).

Part 2[2] contains a series of papers on subjects of special interest. M. Macgregor and J. Pringle discuss the Scottish Millstone Grit in relation to that of the Pennines. The freshwater fauna of the Lower Coal Measures of Lancashire is described and the range of variation of its constituents demonstrated by W. B. Wright. The corresponding fauna in West Yorkshire is dealt with by D. A. Wray and A. E. Trueman. A valuable synopsis of Coal Measure plants and their stratigraphical distribution is provided by R. Crookall. The results of a study of the Carboniferous rocks of Innimore Bay, Morvern, on the Sound of Mull, are recorded by M. Macgregor and W. Manson. The fossils of certain pebbles in the Peel Sandstones of the Isle of Man are shown by H. P. Lewis to be of Salopian age. W. Manson describes the Carboniferous and Old Red Sandstone strata passed through by a boring for water (340 ft. deep) at Stonefold Farm, Berwickshire, with petrographical notes by J. Phemister. Sir John Flett continues his investigations of the teschenite-picrite sills of the Lothians with a study of a thomsonized inclusion from the Blackness sill.

Part 1 of the "Summary" for 1934[3], in addition to the usual information, records the transfer of offices, library and collections from Jermyn Street to South Kensington. The opening of the new Museum in July 1935 was recorded, with an account of the centenary celebrations, in NATURE (136, 75; 1935). Despite the strenuous activity necessitated by the change-over, and the employment of the equivalent of about one third of the field staff in the preparation of exhibits, all the normal departments of the Survey's work were carried on without serious interruption. Maps issued during 1934 number forty-one, and there were published two memoirs, both of which are reviewed below (Ardnamurchan model[5] and Fife Coalfields, Area II[8]). Certain features of the year's work deserve special notice. The colour-printed maps include twelve of the London area on the six-inch scale; fifteen further sheets of the same series were in the press by the end of the year. Among new maps in progress, mention may be made of a series of economic maps of England and Wales on the scale of 16 miles to the inch. Two of the sheets, devoted respectively to the coalfields (exposed and concealed) and iron ores have since appeared. These indicate that the series is likely to be of great educational value, and teachers, in particular, should not overlook this authoritative guide to mineral resources. The most important innovation of the year, however, was the preparation of a series of eighteen descriptive handbooks under the general title of "British Regional Geology". Eleven of the handbooks have now been published and a separate account dealing with them will appear shortly in these columns.

In Part 2[4], Prof. J. de Lapparent (Strasbourg) contributes a most important study of the Carboniferous bauxitic clays of Ayrshire. These deposits contain boehmite and diaspore and it is shown that the conditions of their formation involved the hydrolyzing action of a tropical climate followed by subsidence and burial. It is noted that bauxites which remained exposed during their formation contain gibbsite. W. Edwards describes the Pleistocene dreikanter of the Vale of York, and points out that conditions suitable for such wind-faceting were widespread in Britain and Europe towards the close of the Pleistocene. The strata encountered in a boring (810 ft.) in Northamptonshire are described by B. Smith, the special interest being the discovery of an old floor of presumably Pre-Cambrian quartz-felsite beneath the Keuper Marl. Another boring (980 ft.) at Bushey, Herts, reached Devonian rocks beneath the Gault. The strata are described by F. H. Edmunds; the Palæozoic fossils by C. J. Stubblefield; and the underground water by F. K. Sinclair. One of the most widespread of the fossil-bands of the North-West Province of the Lower Carboniferous is that characterized by *Cyrtina septosa*. It has now been discovered in the Midland Province of Derbyshire and is the subject of a paper by F. W. Cope. Palæontological contributions include a critical examination by K. P. Oakley of a Wenlock coral which has been referred to the Polyzoa by certain authors; a description of a Downtonian eurypterid from Lanarkshire by Dr. L. Størmer (Oslo); notes by C. J. Stubblefield on types and figured specimens acquired from the late S. S. Buckman by the Survey; and an account by W. B. Wright of the large species of *Carbonicola* which characterize the base of the Middle Coal Measures.

The "Guide to the Geological Model of Ardnamurchan"[5] refers to a model, originally constructed for exhibition in the Royal Scottish Museum, which displays the complicated solid geology of the worn-down and long extinct volcano of Ardnamurchan. The horizontal scale is four inches to a mile, but as the highest peak, Ben Hiant, reaches only 1,729 ft., heights have been slightly accentuated by adopting a vertical scale of six inches to a mile. The guide is very fully illustrated and forms a readable introduction to the remarkably interesting features of a Tertiary volcano which is justly famous for the perfection of its ring-structures and the variety and significance of its petrological phenomena. A detailed memoir on the area was published in 1930 (see NATURE, 128, 619; 1931).

The volume descriptive of the underground water supplies of Herefordshire[6] is one of a growing series which now covers the London area and twenty-eight counties. The usefulness and practical value of these memoirs has been especially emphasized by the droughts of recent years. As Herefordshire is a county that depends to a very considerable extent on underground resources for its potable water—whether as feeders of bores, wells and springs, or as contributors to the flow of rivers during dry periods—this latest issue should prove especially welcome. The main rivers are also discussed as sources of supply, and a selection of chemical analyses of the river- and well-waters suffices to show the principal types of water available.

The first edition of the memoir dealing with the Merthyr Tydfil district of the South Wales Coalfield was published in 1904 and has been out of print for many years. The progress of mining and geological research has made necessary a considerable amount of revision in the new edition[7], particularly as regards the zoning of the Carboniferous rocks and the underground structure and correlation of the coal seams. The district includes a large part of the magnificent mountain range of the Fforest Fawr, the highest peaks of which, the Brecknock Beacons, lie just north of the area described. Bare cliffs and numerous river channels clearly display the higher strata of the Old Red Sandstone, together with the Carboniferous Limestone and Millstone Grit formations. The southern part of the region is in Coal Measures and includes the industrial centres of Merthyr, Aberdare and the upper part of the Swansea valley. Special chapters are devoted to economic minerals and to palæobotany.

The second of the series of memoirs describing the economic geology of the Fife coalfields[8] deals with the central part of the county, comprising an area of about a hundred square miles, mainly occupied by strata of Lower Carboniferous age. The structure is complicated by numerous faults and intrusions of igneous rock, while the sequence in the southern part includes considerable thicknesses of lavas and ashes. The main structural feature is the Burntisland anticline, which separates the Cowdenbeath and Lochgelly coalfields on the west from the Kirkaldy coalfield on the east. More than 1,400 bore and shaft records have been collected to elucidate the relations of the formations. Much of the memoir is devoted to the coal-bearing strata of the Limestone Coal Group and the Productive Coal Measures.

The memoir describing the geology of the Orkneys[9] will be generally welcomed because the official survey has only recently been completed and is of special interest on account of the wealth of new information regarding the Old Red Sandstone now made available. The first four chapters deal with the history of geological research, the topography and scenery, and the general geology of the islands which make up the group. The intermediate chapters provide more detailed accounts of the individual districts and islands, while the last three chapters are respectively concerned with fossil fishes, fossil plants and petrography. With the exception of a small area in the neighbourhood of Stromness, where an ancient granite-schist complex occurs, most of the islands are mainly built of flagstones and sandstones belonging to the Middle division of the Old Red Sandstone. These beds were folded and heavily eroded before the deposition of those of the Upper division. The latter are restricted to Hoy and include ashy sediments and olivine-basalt. Five volcanic vents have also been detected in Hoy. The structure of the island-group is comparatively simple, consisting essentially of a central series of synclines passing over on the west into the broad and gentle West Mainland anticline and on the east into a series of minor anticlines. Faulting follows three directions, two of which are represented by the shores of Scapa Flow, where three important faults all throw down towards the sea. Numerous dykes of bostonite, camptonite and monchiquite traverse the Old-Red Sandstone, but their age, as elsewhere in Scotland where similar dykes occur, is still undetermined. The memoir is provided with a bibliography, a glossary of Orkney place-names, and an excellent geological map in colour on the scale of 4 miles to one inch.

t to the Massachusetts Institute
spectroscopic work, contributed to
of valuable personal contacts with
rs in the United States. The visit
included attendance at a conference on spectroscopy, an account of which was read before the British Association. Another grant was used largely in the purchase of Irish parliamentary reports for a study of "British Imperial Policy in the Twentieth Century", which provokes the question: is it not 'up to' Governments, seeing that they stand to benefit from the products of competent disinterested research in the social sciences, to encourage it to the extent, at least, of placing such material gratuitously at the disposal of an investigator of the standing of a university professor of history.

THE Department of Business Administration at the London School of Economics, established a few years ago on the initiative of a group of business men for university men who were resolved on a business career, has had another successful year. An Advisory Council has recently been established to assist in maintaining the closest possible touch between training and current practice. The chairman of the Council is Major-General Guy P. Dawnay, and its membership includes Sir Harold Bellman, Sir Kenneth Lee, Sir Felix Pole, Sir Frank Spickernell and others who are prominent in different fields of finance, industry and trade and who are united in the determination to develop the Department as a centre of business training for graduates of British universities. Interest in the post-graduate course of business training extends beyond those industries represented on the Council, and an American business man has recently given £200 for a studentship for 1936–37 in the fields of investment or finance. The Leverhulme studentship of £200 is also open to competition. Some business firms have from time to time used the Department as a kind of staff college, and others have offered appointments to graduates subject to their first attending satisfactorily the Department's course. Great care is taken to admit to the course only those likely to make good in a business career. There is now apparent a demand among managers themselves for lectures on current problems, and in the winter months of 1936–37 a series of twelve such public lectures will be delivered by six members of the academic staff on matters of administrative organization, business finance, industrial production, distribution developments, marketing and public relations, statistical and accounting service.

A STUDY of education in Czechoslovakia was undertaken by the United States Office of Education two years ago. A report prepared by a specialist in comparative education, S. K. Turosienski, on the basis of visits paid to a great number of types of schools as well as interviews with school authorities and examination of official documents, has been published as Bulletin No. 11 of 1935 (Washington: Government Printing Office, 25 cents). The establishment of a national system of public education was one of the first tasks confronting President Masaryk after the new Republic of Czechoslovakia was constituted in November 1918. The report indicates that the system is working well and contributing powerfully to the prosperity and well-being of the nation. Problems arising from multilingualism—Czechoslovak, Carpatho-Russian, German, Magyar, Polish, Rumanian, modern Hebrew and other tongues are used as languages of instruction—have been solved with remarkable success. Religion is a compulsory subject of study in all elementary, secondary and normal schools, the time allotted for it being, in general, two hours a week. Particular care is taken to exclude influences calculated to inflame racial or national animosity. In all secondary and elementary schools instruction is given in civics, under the headings : national culture, League of Nations, civilization of all nations, general progress of mankind, equality among the races and nationalities, the World Court, international treaties and guarantees, international pacifism, religious tolerance, history of labour and civilization, natural laws, man and the world, conditions of happy, peaceful life, etc. Parental co-operation with the school authorities is legally provided for by means of parents' councils. A noteworthy feature of the system is the clarity with which the objectives of education are set forth, not merely with reference to the educational process as a whole but also specifically for each course.

Science News a Century Ago

Death of Dr. William Henry, F.R.S.

ON September 2, 1836, Dr. William Henry, the eminent chemist, died at Manchester at the age of sixty-two years. The son of Thomas Henry (1734–1816), one of the founders and the first secretary of the Manchester Literary and Philosophical Society, he was born at Manchester on December 12, 1774, and attended the Manchester Grammar School. For several years he was secretary and assistant to Dr. Thomas Percival (1740–1804), the first president of the Literary and Philosophical Society, but, when twenty-one years of age, spent a session at the University of Edinburgh, where he was one of the last pupils of Black. On his return to Manchester, Henry assisted his father in his chemical business, wrote memoirs and lectured, and in 1801 published his "Epitome of Chemistry", which was enlarged and became "The Elements of Experimental Chemistry". It was said that this was the first English work on chemistry which with considerable literary merit combined scientific accuracy. It went through eleven editions. His experiments on the absorption of gases by water were made while he was writing these books. In 1805 he returned to Edinburgh, and two years later was granted the degree of M.D. The remainder of his life was spent in Manchester, where he counted among his friends Dalton.

Henry was elected fellow of the Royal Society in 1808, and in the same year received the Copley Medal. His original contributions to science included papers on medical subjects such as diabetes and cholera, and biographical sketches of Priestley, Davy and Wollaston. At intervals during his life he suffered severely from an accident received when a child, and his death on September 2, 1836, was due to nervous irritation and insomnia. He was a refined, eloquent and accomplished man, and his bust and portrait are preserved by the Manchester Literary and Philosophical Society of which he was an ardent supporter. His life was written by his son, Dr. W. C. Henry.

The British Association at Bristol

SUMMARIZING the results of the Bristol meeting of the British Association, the *Athenæum* of September 3, 1836, said : "Having now read the Reports ; and calmly and dispassionately surveyed the entire proceedings, we are of opinion, that the results of the Bristol Meeting are most satisfactory : rather more than 1,300 members were present, many of the papers read were very valuable, many important questions were discussed, and the Committee have been enabled to devote no less than £2,700, in further aid of science and scientific research. These are beneficial effects not to be questioned. It appears, however, that the Association does not work to the entire satisfaction of some influential members . . . who . . . are of opinion, that some proceedings in particular Sections had a taint of quackery . . . and they are in consequence disposed to limit the sphere of inquiry, or restrict the numbers. Now, we concur generally as to the possible tendency of the Association ; such an opportunity for personal display and cheap advertisement will not be lost by the far-seeing ; but the remedy suggested would be, in our opinion, a still more mischievous error. There can be no such thing as an oligarchy of science, which these restrictions would tend to create. We take leave to suggest the most scrupulous care in the election of Chairmen to the several Sections . . . and a great deal more energy and resolution on the part of the Sectional Committee ; the one (the Committee) should be foreseeing and directing, and the other (the Chairman) the controlling mind of the Association. . . ."

Botanical Society of London

ON September 3, 1836, the *Mechanics' Magazine* said : "A number of botanists, amateurs, etc., have recently held several meetings at the Crown and Anchor Tavern, Strand, for the purpose of forming themselves into a society bearing the above name. . . . Among the leading objects the Society propose are, the advancement of botanical science in general ; the particular cultivation of descriptive and systematic botany ; the formation of a library, herbarium and museum ; the reading of original pa
and translations ; the exchange of sp
other societies or individual collector
other available means that may prom
of the Society". Commenting on th
said : "We are glad to find, among t
of bricks and mortar, ladies and gentl
devoted to so healthy and so endu
botany".

The Flora of Ireland

IN 1836 appeared the "Flora

Jacques Errera, Pol Mollet and Mlle. Mary L. Sherrill: Tetramethylethylene and the influence of the double bond. Study of the infra-red spectrum.

Victor Henri: The electronic state of the radicals in polyatomic molecules. The radicals discussed are SO, CN, $C=C$, NN, and NO. The results relating to the electronic states of the radicals, based on infra-red and Raman spectra, and on the determination of the distance between the atoms of the radicals measured by X-rays or electron rays, can serve as a basis for the analysis of the mechanism of chemical reactions between these molecules. They lead to a new interpretation of the laws of chemical kinetics.

Maurice Bachelet: The extraction of uranium X by precipitation of ferric hydroxide. The exact working conditions are given: the yields vary from 85 to 95 per cent.

Maurice E. Nahmias and Robert J. Walen: Some artificial radio-elements. Results of the bombardment of fluorine and sodium by neutrons.

Hans von Halban, jun. and Pierre Preiswerk: Experimental proof of the diffraction of neutrons.

Georges Carpéni: The dissociation constants of ascorbic acid and of its product of oxidation by iodine.

Alexandre Krassilchik: The use of the uranyl-magnesium reagent in dilute alcohol. Discussion of the errors inherent in this method of determining sodium, and suggestions for their elimination.

Mlle. Jeanne Foret: The synthesis of hydrated mono-calcium silicates under pressure.

Tryphon Karantassis and Léandre Capatos: The hexa-iodotellurates of the aromatic amines and of the heterocyclic bases.

Adrien Perret and Joseph Biechler: Researches on some chlorocarbonates.

Mlle. Jeanne Boulanger: Study of the systems zirconyl oxalate, alkaline oxalates and water.

Pierre Sue: The thermal equilibrium between Nb_2O_5, Na_2CO_3, CO_2.

Georges Dupont and Raymond Dulou: The oxidation of cyclohexene by hydrogen peroxide.

Jules Garrido: The dehydration of brucite.

Jean Wyart and Yeu Ki-Heng: The crystallographic study of some derivatives of tartaric acid. X-ray studies of tartramide, tartramic acid, methyl tartrate and potassium borotartrate.

Pierre Marie: The Cretaceous micro-fauna of the south-east of the Paris basin.

Marcel Roubault: The radioactivity of some natural springs of the Kahylie de Collo (Department of Constantine, Algeria).

Charles Bois: Earthquakes with abnormally deep focus. A table showing focal depth obtained by various authors by different methods.

Paul Corsin: The phylogeny of the Inversicatenales.

Paul Bertrand: Some fundamental observations for the comprehension of the organization of vascular plants.

Roger Heim: The phylogeny of the Lactario-Russula.

Mlle. Jane Manuel: The sexuality of *Hansenula Saturnus* and of some species of the genus *Saccharomyces*.

Marcell Masoré and René Raymond-Paris: The comparative action of acrolein vapour on the cellular structure and glucidic composition of some plant tissues.

Antoine de Cugnac: The experimental production of inter-specific hybrids in the genus *Bromus*, and some related systematic considerations.

Désiré Leroux: The influence of the trituration of cultivated soils on the amount of essential fertilizing principles in their aqueous extract.

Robert Castagné: The improvement of technique [historadiography]. Substitution of a window of lithium for one of aluminium. Lower voltages can be used and exposures shortened.

Emile Haas: Comparison between the energy of a simple radiation and that of a mixture of radiations of the same visual appearance.

Charles Lapicque: The optical structure of the vitreous body.

R. Jonnard: The interferential study of the refraction of blood serum as a function of the concentration.

Stig Veibel and Erik Nielsen: A case of a non-hydrolyzable β-glucoside.

Jean Roche and Mlle. Marie Thérèse Bénevent: The hæmatins of the α-cytochromes.

Théophile Cahn and Jacques Houget: The utilization of glucides in experimental diabetes.

Gaston Ramon and André Staub: A new method of anthrax vaccination.

Moscow

Academy of Sciences (*C.R.*, 2, No. 1, 1936).

S. Michlin: Composition of double integrals.

L. Kantorovich: Some theorems on semi-regular spaces of general type.

B. Demidovich: Existence of an integral invariant in a complex of periodic points.

P. A. Walther and V. A. Stefanovskij: Action of centrifugal forces inside the axial pump.

A. A. Grünberg and B. V. Ptioyn: Titration of bivalent platinum and trivalent iridium at different temperatures.

J. G. Ryss and N. P. Bakina: Complex fluorides. (1) Hydrolysis of the silicofluoride ion.

W. A. Silberminz and A. K. Rusanov: Occurrence of beryllium in fossil coals.

G. M. Smirnov and G. M. Zaridze: Neo-intrusions of the Dzyrul crystalline massif.

A. M. Lebedev and L. I. Sergejev: Regeneration of vernalized plants after injury of the growing points.

I. N. Konovalov: The effect of the vernalization of plants upon the accumulation of organic substance.

S. V. Dorofejev: Observations on the reproduction period of Greenland seals (*Histriophoca*) (*groenlandica oceanica* Lepechin).

A. S. Serebrovskij: An attempt at a new method of genetical analysis of quantitative characters.

(*C.R.*, 2, No. 2, 1936).

P. S. Alexandroff: Contribution to the theory of topological space.

B. Z. Vulich: Some remarks to the theory of K-normed space.

V. Rasumuvskij: Latent polarity and explicit polarity of molecules.

L. W. Nikitin: Acoustico-electrochemical phenomena (2).

I. N. Nazarov: Metal-ketyls of the fatty series. (4) Action of metallic sodium on *tert.*-butyl-*tert.*-amyl and *tert.*-butyl-*tert.*-hexyl ketones.

* *Continued from p.* 338.

T. N. Godnev and **S. V. Kalishevich**: Quantitative determination of chlorophyll with the aid of the light of a Lange electrical colorimeter.

P. G. Danilchenko: Ecology of the spawning migrations of the salmon.

Washington, D.C.

National Academy of Sciences (*Proc.*, 22, 327–434, June 15).

Frederick H. Seares: Selective absorption of starlight by interstellar clouds. Measures of the colours of certain stars in luminous or dark nebulosities show them to be redder than would be expected from their spectral types. This seems to be due to selective absorption of light, and quantitatively it is sufficient to require a radical change in the estimated dimensions of the stellar system.

Cecilia Payne Gaposchkin: On the physical condition of the super-novæ. Their spectra are similar to those of ordinary novæ, but with wider bright lines. It is concluded that they differ from novæ mainly in size, having possibly developed from giant stars.

E. S. Castle: A model imitating the origin of spiral wall structure in certain plant cells. Six wooden dowels are fixed in a wooden base and their free ends separated by a small wooden spool. A ring pushed down over the dowels produces a spirally twisted formation, which seems to be similar to that of the wall of the spore-bearing cells of Phycomyces.

Nathaniel Lyon Gardner: A new red alga from New Zealand. It is parasitic on *Zostera* and has two forms, one having erect filaments (*Erythrocladia Hunteriæ*).

N. L. Bowen and **J. F. Schairer**: The system albite – fayalite. The mixture is heated in a crucible suspended in a platinum resistance furnace, and the temperature of appearance of a phase is determined by quenching the charge in mercury and examining it under the petrographic microscope to determine the phases present. The diagram for albite – fayalite is of simple eutectic type. It is hoped to use the marked fluxing action of albite to examine the equilibrium relations of other silicate mixtures.

M. Demerec: Frequency of 'cell-lethals' among lethals obtained at random in the *X*-chromosome of *Drosophila melanogaster*.

Aleš Hrdlička: Puberty in Eskimo girls. The age of onset for 16 full-blooded Kuskokwim Eskimos (Alaska) and also of 6 mixed-bloods is 13½ years, which is unexpectedly low for so far north.

Froelich G. Rainey: Eskimo chronology. A test cut to a depth of fourteen feet through a stratified midden deposit at Kukulik, St. Lawrence Island, Alaska, has revealed six cultural horizons, most of which have been recognized at widespread Eskimo sites in the Arctic.

William Hovgaard: Torsion of rectangular tubes. Current theory, based on a hydrodynamical analogy, represents the angle of torsion correctly up to the point of breakdown, but gives an incorrect picture of the stress distribution.

R. Courant: (1) On the problem of Plateau. (2) On the theory of conformal mapping.

G. A. Miller: Regular subgroups of a transitive substitution group.

Hans Lewy: Generalized integrals and differential equations.

J. W. Alexander: On the connectivity ring of a bicompact space (2).

Food Requirements in the Modern State

THE Health Committee of the League of Nations has given abundant evidence during the past few years of its interest in human nutrition. The health experts who were asked last year to formulate guiding principles for the construction of adequate human diets emphasized the importance of the provision of ample supplies of protective foods, especially dairy produce, fresh vegetables and fruit, for the purpose of securing an optimum state of nutrition. The problem of securing such supplies for the masses of the populations of modern States must involve in most instances far-reaching changes in economic and agricultural policies. A mixed committee was accordingly set up, composed of economic and agricultural experts, in addition to health experts, under the chairmanship of the Viscount Astor, to report on the whole position regarding the relation of nutrition to health, from the point of view of practical politics. The Committee has now issued the first volume of its report[*], which provides a general survey of the problem.

In the light of the established principles of nutrition, it can be shown that in no country does the whole population attain the scientifically desirable standard of physical development or resistance to disease. To remedy this serious defect, the greatest emphasis ought to be laid on the proper feeding of pregnant women and of children, for many individuals bear throughout life the stigmata of defective feeding in childhood. This would involve a campaign of education in which public health officials, practitioners of medicine, health nurses, school teachers and social workers should co-operate. Economic and agricultural policies would have to be framed by the Governments concerned, to enable the necessary food to be produced and distributed. The campaign for better nutrition should take its place as an integral part of national policy. Such a policy would require for its effective working the supervision of a central authority which would secure the co-operation of bodies engaged in nutritional research, of those engaged in popular instruction and of those responsible for directing economic and agricultural policies.

The main body of the report deals in simple language with the dietary requirements of human beings of different classes and age-groups, and gives illustrations of some of the observed effects of improper feeding on the physique and health of individuals and communities. This section is followed by chapters dealing with some of the economic and agricultural aspects of the problem of nutrition. These chapters are short, for the reason that later volumes of the report will deal more fully with these particular aspects.

In the last section of the present volume, the Committee formulates recommendations which it invites the Assembly of the League of Nations to approve, in the hope that they may be accepted by Governments and may make an immediate contribution towards the improvement of nutrition among the peoples concerned. These recommendations urge the policy of encouraging the scientific study of nutritional problems and of furthering the dissemination of knowledge so gained. International co-operation is invited to facilitate the exchange of relevant information. Governments are also urged to consider what steps might be taken to meet the nutritional requirements of those sections of their communities with the lower ranges of income, and particularly to ensure an adequate supply of safe milk for expectant and nursing mothers, infants, children and adolescents. Further recommendations include the examination of schemes to make supplies of the protective foods available at prices within the reach of all classes without prejudicing the interests of producers. If necessary, the question of the re-orientation of agricultural production, with the view of satisfying the requirements of sound nutrition, should be seriously considered.

Malaria and Nutrition

THE Royal Society, more than thirty-five years ago, followed up Ross's discovery of the mosquito-cycle of the malaria parasite by sending specially qualified research workers to Africa and India to study the endemiology and epidemiology of the disease and the life-history and habits of the mosquitoes which transmit it. Judged by the results of those investigations, which were published as Reports to the Malaria Committee of the Society between 1899 and 1903, the action was one of the most important steps ever taken for the advancement of knowledge of the subject. The Society has recently taken a second step which everyone will hope may have an equally important outcome. At a meeting held in July this year, the Council decided that the whole income, together with the invested income, of its Medical Research (Anonymous) Fund should be employed for a period of five years on a scheme of laboratory research on malaria to be conducted in England, and a field inquiry into malnutrition to be conducted in India. The two subjects are more closely related than may be apparent, for it has been shown repeatedly in Italy and elsewhere that measures designed to improve the nourishment and general welfare of the people have a great effect in lessening the mortality, disability, and other evils due to acute or chronic malarial infection.

The scheme as a whole is estimated to cost about £8,500 for the period mentioned, and has been worked out and arranged for in detail. The malaria programme is in two parts, of which the first is concerned with the parasites and their relationship with human, animal and insect hosts, the second with the ecology of one or more of the species of anopheline mosquitoes chiefly responsible for spreading malaria in the tropics. On both subjects an advanced type of scientific 'long-range' research by modern experimental methods is contemplated. It is believed that in the present state of knowledge this highly specialized type of work offers the best hope of improving existing methods of dealing with malaria, and it is recognized that its pursuit has been facilitated during recent years by several outstanding events such as the application of the practice of malariatherapy to the study of malaria itself, as well as for its original purpose, and the discovery that monkeys, as well as canaries and other birds, can be utilized for studying immunological and other problems. It is intended, too, to give increased attention to the chemotherapy of malaria, which has become of paramount importance since the discovery of effective synthetic anti-malarial remedies, and is a subject on which, up to the present, little has been done in Great Britain (see NATURE, Nov. 9, 1935, p. 743).

The practical object of the proposed research into the ecology of a particular species of anopheline mosquito is to improve the antimalarial method called 'species sanitation', which aims at the elimination from an area of the species that has been found to be most concerned in transmitting the disease. Success in this task would be greatly facilitated if complete knowledge were available of the biology, habits and behaviour of the insect concerned, and particularly if the physical, chemical and other factors governing its choice of breeding places, food supply, shelter and other items of behaviour were precisely known. Thanks to new methods devised by insect physiologists, these problems can now be studied experimentally in the laboratory and applied to observations made in the field.

Lieut.-Col. J. A. Sinton, I.M.S., lately director of the Malaria Survey of India, has been appointed to conduct the first part of the malaria programme, and it has been arranged that he will work in the laboratories of the Malariatherapy Centre at Horton where, in addition to the intensive study of particular problems, he will have an opportunity of continuing and extending the observations on induced malaria which it was feared might have to be given up when Colonel S. P. James retires this year.

The second part of the programme is to be commenced in the Entomological Department of the London School of Hygiene and Tropical Medicine by the appointment of a young worker with experience in modern experimental zoology. For a period of 12–18 months he will study the physiology and behaviour of the several species of anopheline mosquitoes which can be made available in England, and will then proceed to an appropriate centre in India for the special research proposed. It is understood that the London School has undertaken to meet part of the cost of this research.

Dr. Curjel Wilson has been appointed to conduct the nutritional survey in India in collaboration with Dr. Aykroyd, director of nutrition research to the Indian Research Fund Association. The survey will be concerned chiefly with the incidence of malnutrition among school children, and the dietary habits of groups of families in the districts where the children live. An important object of the investigation will be to train workers who will continue and extend the survey.

It may confidently be expected that the expenditure from its trust funds by the Royal Society which this programme involves will be fully justified by the additions it will make to our knowledge of malaria, which, despite all that has been done during the last three decades, still remains the greatest single destroyer of the human race.

Nature and Purpose of Science

The Scientist in Action:

a Scientific Study of his Methods. By Dr. William H. George. Pp. 355. (London: Williams and [illegible] Ltd., 1936.) 10*s*. 6*d*. net.

THE reviewer's first task is to state the nature of the book and the purpose of its author. Here this task is very difficult. "Action" is the key-word of the title; and on his first page, Dr. George tells us that he takes it "as basic that scientific research is a form of human action". But he has just said that "by definition speaking, writing or manipulation . . . are forms of action but thinking, believing or feeling are not." Research then, for Dr. George, is an activity in which thought and belief play no part. This is sufficiently puzzling; but it becomes more puzzling when most of the book is found to be concerned with things that are indubitably thought or believed and not *done*—laws, theories, propositions in general, and so forth.

This inconsistency pervades the book. A possible (but of course speculative) explanation is suggested by hints in the final section. It is that Dr. George started to "clarify his mind on the relation between experiment and theory, and more especially on the relation between experimental and mathematical physics"—in other words, to solve the central problem of the philosophy of science. Reading the works of his forerunners, he was repelled (as many others have been) by the folly of those to seek to interpret science as a set of formal propositions out of any relation to the scientists who produce them. He therefore rushed to the other extreme and, "to his own surprise", arrived at the conclusion that science, though "inseparable from scientists, is quite separate from philosophy". In order to understand science, all that is necessary is to study the scientist reacting, like any other organism, to its environment; his problem turned out to be purely biological.

Of course, Dr. George could not act consistently on such a belief. Mental activity is even more difficult than physical activity to describe without some preconceived scheme to which it is supposed to conform; and even if a perfectly neutral description of the mental activity of a scientist could be given, it would not explain that activity or clarify anyone's mind concerning it. For that task it is necessary to show that the activity does conform to some logical scheme that is equally valid for all kinds of thought; the ordering of different kinds of thought into a single coherent whole is not merely inseparable from philosophy; it actually is philosophy. Accordingly, Dr. George found himself alternating between his new desire to ignore all forms of activity that cannot be merely described, and his old desire to clarify his mind; his book is a queer medley of his two moods.

Dr. George's work in his old mood does not appear to me very valuable. He has made the common mistake of being so preoccupied with those at the opposite extreme of thought as to ignore altogether those who stand very near to his own point of view. Thus, he might have been expected to find Bridgman's "operational" doctrines sympathetic; he makes no reference, explicit or implicit, to Bridgman, but expresses approval of Hobson, who really agrees with him in nothing but a common dislike of transcendental metaphysics.

The book is divided into three main sections: the scientific outlook, getting scientific facts, arranging scientific facts. What Dr. George has to say on the topics to be expected under these headings is neither very original nor very profound; it is difficult to summarize, because so much of it is merely negative. Science is *not* based upon measurement; the "coincidence observations", constituting the facts on which it is based, are *not* merely temporal or spatial; the observables of quantum theory are *not* what is actually observed; mathematical probability is *not* a measure of rational belief. But the positive assertions that might be expected to supplement these negations are lacking; after the last of them "the reader is left to decide" what, if any, is the connexion between probability and belief—surely a matter vital to any understanding of science!

In his new mood, however, Dr. George is a very different person. His description of scientific activities is always accurate and, though there are many commonplaces, often acute. He does not, of course, profess to instruct researchers in their art, but few of them could read the book without gaining some useful hints; at any rate they will be soothed and entertained by finding all their instinctive prejudices set forth so sympathetically.

However—this may possibly shock Dr. George—the persons who will gain most from his work are precisely the philosophers whom he treats with such contempt. For many of them accept fully Dr. George's main thesis that science is incomprehensible apart from scientists. But they find it difficult to discover how scientists really think. Lack of technical knowledge forbids them to study the original literature of science; while those distinguished men who undertake to explain science to the unlearned are notoriously untypical; indeed their success as popularizers is largely due to their sympathy with views that most scientists reject emphatically. Their difficulty is now completely solved. Dr. George is a thoroughly typical scientist—typical, not of all scientists (that is impossible, because scientists differ), but of those to whose mental idiosyncrasy the distinctive character of science is due; and he has been marvellously successful in portraying their method of thought.

Accordingly, if anyone in the future writes about the nature and purpose of science, meaning thereby that which scientists produce, without careful study of Dr. George's book, he will be wasting his own and his reader's time. But of course he will find himself in a difficulty. For what distinguishes the true scientist is a hatred of abstract thought and of the shackles of logic. The discovery of an intellectual difficulty delights the philosopher; it makes Dr. George and the rest of us go all hot and bothered. If this dislike of logical precision is a necessary element of the scientific outlook, there can be no philosophy of science; if a scientist who was willing and able to untie the intellectual knots in which he is constantly entangling himself, would thereby [illegible] be a scientist, then there can be no place fo[illegible] in any scheme of ordered thought. If, on the other hand, this attitude is unnecessary and inessential, if science is really subject to a logic which alone can make it intelligible, how do scientists manage to produce science? The great merit of Dr. George's book lies in its raising this problem so clearly; it is for others to solve it.

NORMAN R. CAMPBELL.

The People of Pitcairn Island

The Heritage of the Bounty:
the Story of Pitcairn through Six Generations. By Harry L. Shapiro. Pp. xv + 330 + 8 plates. (New York: Simon and Schuster, Inc.; London: Victor Gollancz, Ltd., 1936.) 3 dollars; 10*s.* 6*d.* net.

PERENNIAL interest in the story of Bligh and the mutineers of the *Bounty* has been enhanced recently by the cinematograph; but Dr. Shapiro, though fully alive to the drama of the story, of which he recalls the main outlines, is more immediately concerned with the opportunity afforded science by the consequences of this tragedy of the sea. While still *in statu pupillari*, he was inspired by Prof. E. A. Hooton of Harvard with an overwhelming urge to biological and sociological investigation among the descendants of the mutineers and Tahitian women living on Pitcairn Island. He had to wait twelve years before his desire was satisfied. Although he visited Norfolk Island in 1923, and spent five months examining the Pitcairn Islanders and their descendants who had been transported there in 1856 —the results were published in 1929—it was not until 1934 that he was able to land on Pitcairn.

Pitcairn Island, it will be realized, offers exceptional opportunity for the study of miscegenation and the effects of culture contact. The islanders are the descendants of six mutineers and thirteen Tahitian women. The six Tahitian males left no offspring. Although the descendants of the migrants to Norfolk Island are the more numerous, conditions on Pitcairn are more favourable to scientific investigation, as the accessions of new blood there have been few and are known—eight Europeans and one Polynesian female. The records of birth, marriage and death have been kept with care, while genealogical data are remembered with pride—and no less well remembered when calling for a veil of reticence. Another advantage from the point of view of the observer is that the material is entirely unaffected by the social disabilities which usually depress the products of racial crossing elsewhere and vitiate observation.

It is a remarkable fact, perhaps the most striking fact in the vital statistics of the island, that the increase in population has been extraordinarily rapid. In one hundred and forty-five years from the original matings, the living descendants of the mutineers now pass the eight hundred mark. There are more than six hundred living on Norfolk Island and some two hundred on Pitcairn; and if absentees were taken into account, the figure might well fall not far short of a thousand. The [redacted]erations seem to have been extraordinarily A calculation by Dr. Shapiro gives in his group of women, listed according to years in the period 1815–39, an average family of 11·2. It was owing to this rapid increase in numbers, which threatened over-population, that the Pitcairn Islanders were transported to Norfolk Island in 1856. Of those transported, forty-two had returned to Pitcairn by 1864; and from them the present population is descended. The continued rapid increase in numbers during the last seventy years is thought by the islanders again to threaten over-population; but Dr. Shapiro is of the opinion that the danger is not imminent. His analysis shows that the rate of increase is falling with a falling birth-rate.

Although inbreeding naturally is intense, no ill effect is perceptible, except possibly deterioration in the teeth. It may be responsible for a degree of homogeneity in physical character unusual in such a population of mixed origin.

The evidence of cross strains in physical character is interesting. The two stocks were markedly differentiated, and the strains on both sides certainly not inferior. The English probably were picked men. While the men of the present day incline to favour their European ancestry, as, for example, in the tendency to a lighter coloured eye, the women favour the Tahitian. In them the dominant in eye colour is brown. In skin colour there is an overlap with both English and Tahitian. While none is as dark as the darker Tahitian, few individuals are as fair as the fairest English. In stature the men are taller than either the Tahitian or their European ancestors, of whom the height is recorded at the Admiralty. The head-length is almost identical with that of the Tahitian, being less than that of the English head; but in breadth they follow the English measurement and are narrower than the Tahitian. The cephalic index is intermediate between the two. It is interesting to note that the characteristic disproportion between the frontal diameter and broad face found in the Tahitian appears also in Pitcairn, although the facial breadth is low as in the English. Consequently in the Pitcairn islander the frontal diameter is lower than in the Tahitian, and still more so than in the European.

Dr. Shapiro sums up his results as showing that in their heredity the Pitcairn Islanders bear testimony to both their English and their Tahitian ancestry; and while some are more influenced by the Tahitian strain, some by the English, others appear to be intermediate. Each one is a varying mixture of characters, of which some follow the Tahitian, others the English character. On the whole, the features of the islanders are definitely English. This preponderance is only natural, the author concludes, as all new additions to the colony have been of English stock. Fortunately, the researches in the Pitcairn records made by Dr. Shapiro, which are here embodied with material from outside sources in a history of the islanders from the time of the first settlement, enable all such additions to the original strains to be traced and checked.

It is interesting to note that the author is decidedly of the opinion that the results of his investigation support the view that an early result of miscegenation is an increase of vigour transcending that of either of the original stocks.

Dr. Shapiro has recorded a number of phrases of the Pitcairn language, which he regards as a hybrid dialect. His evidence scarcely bears this out; and a closer knowledge of colloquial English tradition might have convinced him that it does not attain even the dignity of a dialect. It seems to be a mispronounced and degenerate English with a few Tahitian words and mannerisms.

The present-day culture is a blend which shows evidences of development, when compared with that recorded by early visitors to the island. The absence of European materials and appliances in the beginning naturally has affected the balance between English and Tahitian.

Dr. Shapiro is to be congratulated on the opportunity for this first scientific study of unique material, and on the use of it which he has made.

Some British Cœlomycetes

British Stem- and Leaf-Fungi (Coelomycetes): a Contribution to our Knowledge of the Fungi Imperfecti belonging to the Sphaeropsidales and the Melanconiales. By W. B. Grove. Vol. 1: Sphaeropsidales, to the end of the Sphaerioideae which have Colourless or nearly Colourless Spores. Pp. xx+488. (Cambridge: At the University Press, 1935.) 21*s*. net.

IN this handbook, Mr. Grove monographs the recorded British species of this most obscure group of the fungi, a task that has not been attempted in Great Britain since 1871. His Cœlomycetes comprise the Sphaeropsidales and Melanconiales sections of the Fungi Imperfecti, most, if not nearly all, of which are no doubt Ascomycetes classified in their imperfect as opposed to their perfect condition.

The modern systematic mycology of this group really dates from vol. 3 of Saccardo's "Sylloge Fungorum", which appeared in 1884. It is perhaps impossible for us at this date to envisage the state of affairs before Saccardo collected together all the recorded nominal species and put them upon his mycological map, but we may properly recall the cheer with which Mr. Grove greeted the appearance of this volume. In the *Midland Naturalist*, 9, 127 (1886), he tells us how, as about to vault a fence, he observed myriads of black specks on the bark of the top pole; how he deduced in the field that the pole must be mountain ash; how at home the black specks resolved themselves into the pycnidia of *Rhabdospora* as judged by their spores and habitat; and how he turned "to that monument of Herculean labour, the Sylloge Fungorum omnium of Professor Saccardo . . . who stands head and shoulders above all the other mycologists of the age". *Rhabdospora inaequalis*, Sacc., it was, for it agreed in the characteristic pycnidia, the spores and the habitat, and as further evidence there was Saccardo's excellent representation. "Now my task is smoothly done. No link in the chain is wanting. We have determined our fungus with a degree of certainty that cannot always be attained, and are still further rewarded by finding that it is a species new to Britain".

Some forty-eight years have passed, and Mr. Grove presents us with the first half of his monograph of British Cœlomycetes; and—as a monograph must of course—it contains numerous species that cannot be determined with the same certainty that marked the recognition of *Rhabdospora inaequalis*. In Cooke's "Handbook", two hundred species were recorded as British; in this and the second volume which is shortly to follow, more than two thousand nominal species are listed. All the included species have been examined microscopically unless the contrary is specified, the material, on which this work is based, being represented by the collections at Kew and the British Museum, and by more than three thousand collections in the author's private herbarium. At long last, we have a good general idea of what has been found in Great Britain, together with what a most experienced naturalist has made of it.

Mycology is a term that is now held to cover many pursuits, but, broadly speaking, fungi can be studied in the field, in herbaria, in laboratories and in books. The work under notice is the result of some fifty years' ardent collecting and examining at home, checking determinations with authentic material, and a wide knowledge of the systematic literature. The laboratory side of the science, which has developed so strongly of late—especially since the Great War—is left to others.

Saccardo's ground plan, laid down in vol [illegible] "Sylloge", is accepted absolutely, the most [illegible]ant change following on the general recog[illegible] the genus *Phomopsis*, to which a large nu[illegible] nominal species have in recent years bee[illegible]ferred. It does not appear that any othe[illegible] was open to anyone who intended to pr[illegible] orderly account of British Cœlomycetes, and surely it is high time that such an account should be presented. This classification—and it is the only one yet devised—is largely a habitat classification; that is to say, Cœlomycetes which fruit on leaves are apt to find themselves in another genus from those that fruit on stems; pycnidia formed on the surface of wood are not normally classified in the same genus as those that develop just beneath the periderm. As is well known, fungi in pure culture are apt to present little resemblance to their appearance in their natural habitat—the appearance under which they have been discerned, collected, described, classified and preserved in herbaria. It is, therefore, much safer to attempt the identification of a Cœlomycete, in the first instance, before, rather than after, isolation. If this elementary precaution is not taken, there is no known method of ensuring that any systematic data that may be acquired will be comparable to the data preserved in the existing diagnoses of fungi. Such, at any rate, is Mr. Grove's message to the culture men, whom, after a characteristic implement of their craft, he dubs the "petri-petallists".

Together with the ground plan, the author accepts Saccardo's usage of generic names, and will have no nomenclatorial grit thrown into the works, especially by the new type species method of fixing genera (he gives no type species for the genera). As examples, see his citation of the genus *Phoma*, and his inclusion of *Hendersonia elegans* Berk., the type species of *Hendersonia*, in the genus *Stagonospora*, with a footnote that it will probably prove to be neither a *Hendersonia* nor a *Stagonospora*.

As with genera, so with the view of specific values, current for so many years after the appearance of the "Sylloge", but in this case with a note of hesitation. "Generally, in these pages, the host will be made the supreme test" but "in the genera *Cytospora*, *Phomopsis*, *Septoria* and the like, the list of presumed species cannot be considered as anything but an interim catalogue of the known and described forms". It is probably on this question of specific distinction that systematically directed culture work could be of the most immediate use to a study of the Cœlomycetes. For example, a *Phomopsis* is usually, if not always, the pycnidial condition of a species of the ascomycete genus *Diaporthe*. Mr. Grove lists about 158 nominal British species of *Phomopsis*. In a recent world monograph of *Diaporthe*, Wehmeyer has suggested that the type species, *D. eres*, which was first described on *Ulmus*, really occurs upon nearly all woody plants, and has (ominously enough) acquired about 160 synonyms. The question as to the number of good British species of *Phomopsis* is obviously open for research by anyone who cares to collect, determine and isolate these common and easily grown fungi. Pending any such study, Mr. Grove will probably agree that we are still very much in the position so graphically described by Saccardo, when he was roughing out the classification of the Fungi Imperfecti. "Et in Mycologia fere omnes tyrones sumus."

The citation of literature is terse. The standard floras appear as "All.", "Died." and "Mig.". B. & Br. stands for Berkeley and Broome and B. & V. for Berlese and Voglino. The original place of publication is often not given, especially with Saccardo's own species which later became incorporated in the "Sylloge", vol. 3. The author has been misled into thinking that the dates on the title pages give the correct dates of many species that were founded by Allescher and Diedicke. These, however, are points of nomenclatorial compilation, and the interest of the book is wholly taxonomic; it has, in fact, quite clearly grown out of a lifetime's comparison of the British flora with the diagnoses in a well-thumbed and well-loved copy of vol. 3 of the "Sylloge".

In common with all the foundation mycological books of any country, the present volume has required of its author a knowledge of our local phanerogams in bud, in leaf, in flower, in fruit and in decay—especially in decay. It appears to me that it will be welcomed by all British botanists who believe that the plants themselves, and the fungi themselves, are the thing. It is a milestone in our slow—our very slow—advance in the study of the microfungi. It may happily help to dispossess the commonly copied figures of a few fungi of their predominating influence on the young idea. It may even serve to distract attention from hypothesis and speculation and direct it rather to the original source of mycology itself—the yearly pageant of our woods and fields.

E. W. MASON.

Crustacea:

Anomura, Macrura, Euphausiacea, Isopoda, Amphipoda and Echinodermata: Asteroidea and Echinoidea. By Lee Boone. (Bulletin of the Vanderbilt Marine Museum. Volume 6: Scientific Results of the World Cruise of the Yacht *Alva*, 1931, William K. Vanderbilt commanding.) Pp. 264+96 plates. (Huntington, L.I., N.Y.: Vanderbilt Marine Museum, 1935.)

THE present volume relating to Crustacea and Echinodermata collected by Mr. Vanderbilt and deposited in his museum is full of interesting material. Careful descriptions and good figures are given of every form described. The larger crustaceans are already known, but much new matter is added, and among the Caridea there are many new species. These last were mostly taken in coral and include a *Leptochela*, an *Athanas*, *Alpheus* spp., a *Coralliocaris*, a *Thor* and a *Pontophilus*, besides a pontoniid which the author has referred to a new genus which she has named *Vanderbiltia*. Besides all these new species, many little-known forms are redescribed. There are also two new species of *Euphausia*. Some isopods and amphipods are included.

Among the most striking of the Caridea is the pontoniid *Conchodytes biunguiculatus* Paulson, which was found inhabiting the pearl oyster *Meleagrina* sp. Its peculiarly modified hind legs (pereiopods 3–5) end in large hook-like claws, presumably for clinging to its host, and the abdominal terga of the female are very broad, forming a brood pouch, which holds 75–100 young.

The echinoderms must be magnificent, judging from the exquisite photographs, especially the sea-urchins.

Molekülspektren und ihre Anwendung auf chemische Probleme

Von Prof. Dr. H. Sponer. 1: Tabellen. Pp. vi+154. 17.60 gold marks. Teil 2: Text. Pp. xii+506. 37.80 gold marks. (Struktur und Eigenschaften der Materie, Bd. 15, 16.) (Berlin: Julius Springer, 1935–36.)

THERE is a good deal to be said in favour of the manner in which Prof. Sponer has arranged the material which he discusses in these two books. The first is really an appendix or collection of results for use in conjunction with the description of the applications of band spectra to chemical problems in part 2, and consists of a series of tables of the terms of spectra emitted by polyatomic molecules. Similar tables were, of course, given in Jevons's "Report on Band Spectra" for diatomic molecules, but the Sponer collection for more complicated molecular systems is new, and the data for diatomic molecules have been brought up to date. While it appears unlikely that the descriptive matter in the five hundred page Part 2 will soon need serious revision, it should be a relatively easy matter to add fresh results in a new edition of the one hundred and fifty page Part 1.

Part 2 is intended to assist experimenters, and there is little attempt at serious mathematical treatment of the subject. It opens with a brief, but good, introduction to the older quantum theory of spectra and to the new quantum mechanics, and continues with an excellent survey of the several types of band spectra and their peculiarities. The main interest lies in the examination of the methods and results of band spectra measurement and the chemical and physical data which can be obtained from them, and in the discussion of their importance in problems of chemical combination and valency. Considerable attention is paid to the methods by which molecular spectra are excited and to photo-chemical reactions. The book is bound to appeal considerably to chemists and to physicists who are interested in the applications of band spectra.

Destiny and Disease in Mental Disorders:

with Special Reference to the Schizophrenic Psychoses. By Prof. C. Macfie Campbell. (Thomas W. Salmon Memorial Lectures.) Pp. 207. (London: Chapman and Hall, Ltd., 1935.) 10*s.* 6*d.* net.

PROF. MACFIE CAMPBELL, who is professor of psychiatry at Harvard University, gives us a very readable account of personalities struggling against the difficulties of their environment, particularly with reference to the schizophrenic psychoses, which are a particular type developing in early adult life. This comes as quite a relief when contrasted with lengthy dissertations on infected bowels and sinuses. We feel on reading all these books on mental disorder that the problem in many ways has not even yet been stated, far less grappled with. There are so many factors involved, and we know so little. The writer, however, points out the importance of the environment and its manifold reaction on personalities, many of which we feel were already psychopathic in build.

Insect Enemies of Shade-Trees

By Prof. Glenn W. Herrick. Pp. x+417. (Ithaca, N.Y.: Comstock Publishing Co., Inc., 1935.) 5 dollars.

THE name of Prof. G. W. Herrick, of Cornell University, as a guarantee for a sound, trustworthy textbook is fully substantiated in the present volume. It brings together much scattered information regarding the insect pests of shade trees east of the Rocky Mountains and most of those on the Pacific coast. The economic values of each species of tree are discussed and the most effective control measures against their chief enemies are dealt with. For the most part, each species of tree, with its insect invaders, forms the subject of a separate chapter while, at the end of the book, pests of the smaller trees and shrubs, and some miscellaneous enemies, are dealt with collectively. In so far as certain of the species of insects mentioned are of European origin, the book will interest English readers, while the control measures advised are often applicable on this side of the Atlantic Ocean. The book is admirably printed with 331 clear text figures, which are mostly original. Considering the excellence of its general 'get up', the book is reasonably priced at five dollars.

Hydrostatics:

a Text-Book for the use of First Year Students at the Universities and for the Higher Divisions in Schools. By A. S. Ramsey. Pp. viii+169. (Cambridge: At the University Press, 1936.) 7*s.* 6*d.*

THIS volume has been specially prepared for the use of first year students in universities and for pupils reading for scholarships in the higher divisions of schools. It is thus a companion volume to the author's books on dynamics and statics, which have been published in recent years. The course well covers the academic requirements in the subject, and includes some simple applications of the metacentre, together with a brief discussion on capillarity. A working knowledge of the calculus is assumed, and there are numerous exercises provided for the student, many of which are taken from Cambridge examination papers. Answers to these are given where necessary. The text is illustrated with clearly drawn diagrams and elegantly worked-out examples. The book is admirably suited to its purpose.

Outlines of General Psychopathology

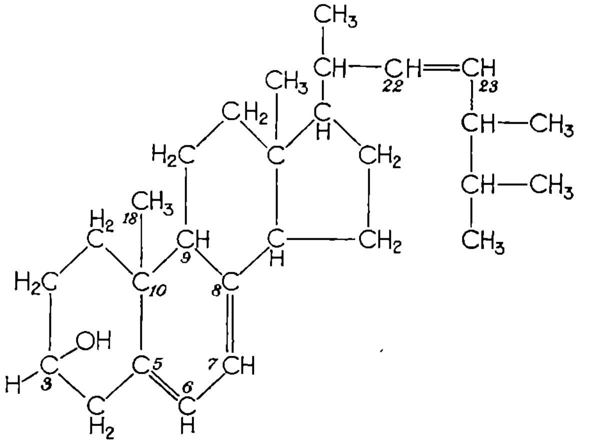
By Prof. William Malamud. Pp. xiv+462. (London: Chapman and Hall, Ltd., 1935.) 21*s.* net.

PROF. W. MALAMUD, who is professor of psychiatry in the State University of Iowa, gives a very readable and useful account of the principles of general psychopathology. We wish, however, that he had enlarged somewhat on the physiological concomitants: action currents, particularly the Berger rhythm, chronaxie, and the psychogalvanic reflex are all subjects about which the reader will want to know more than the author gives us—a mere page for the three.

The chapter on the psychopathological disturbances of sleep is very well done.

Chemistry of Calciferol and Vitamin D_3

CALCIFEROL (Windaus's vitamin D_2) and ergosterol have, according to the view accepted to-day, the formulæ shown in II and I below, respectively.



I

The important common features of the two molecules are:

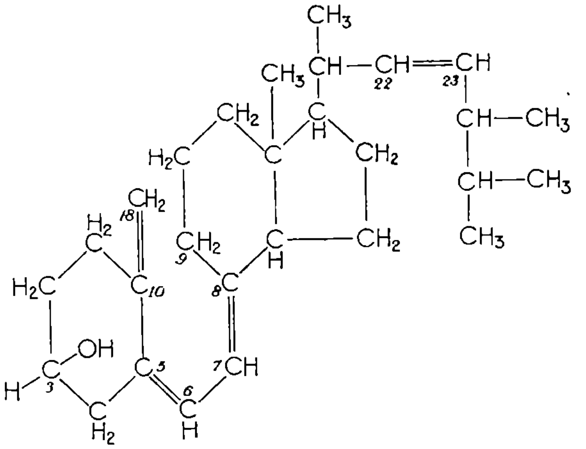
(*a*) The possession of two conjugated double [illegible]nds at $C_5{=}C_6$ and $C_7{=}C_8$.

(*b*) The possession of a hydrocarbon chain containing a double bond at $C_{22}{=}C_{23}$.

The two substances differ in one fundamental respect, namely, the fracture of ring *B* between carbon atoms 10 and 9 and the replacement of the methyl group containing carbon atom 18 by a methylene group, with the consequent introduction of a third conjugated double bond between carbon atoms 10 and 18. It is also possible, indeed probable, that the hydroxyl group at carbon atom 3, which is present in ergosterol—and in all other naturally occurring sterols—in the *trans* position (making the sterols members of the cholestanol series), occupies the *cis* (*epi*) position in calciferol. The point seems not yet to be settled.

A series of papers just published by Windaus and his Göttingen colleagues* is another landmark in vitamin chemistry. They report the logical conclusion, or almost the conclusion, of investigations that have been conducted at Göttingen during the past four or five years.

For some time it has been believed, on the basis of differential biological experiments with two species of animals, that the vitamin D of cod-liver oil is not calciferol. (Bills goes further and maintains that at least *two* separate antirachitic substances occur in fish-liver oils, in different proportions according to the species of fish.) Attempts to isolate this substance have so far been unsuccessful, though claims for a very high degree



II

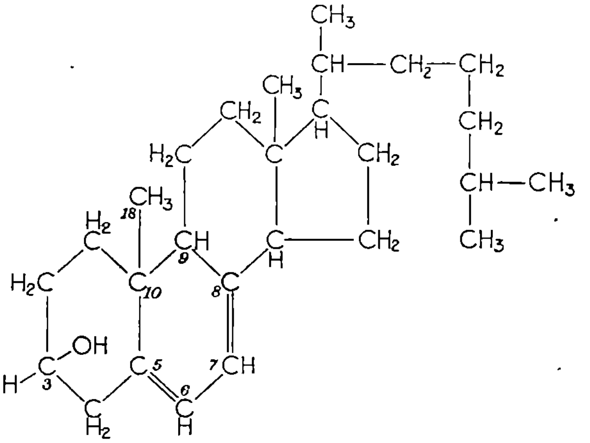
of concentration have been made, notably by Rygh and by Ender.

A crystalline 3,5 dinitrobenzoate of this vitamin, and a colourless non-crystalline preparation of the hydrolytic product from the ester, have now been prepared by Brockmann. The source was tunny-liver oil. The activity of the liquid vitamin is stated to be 25 × 10^6 I.U. per gram, but it is not inconceivable that traces of impurity may be responsible for its failure to crystallize, and the pure compound may prove to be more active. The absorption spectrum is very similar to that of calciferol, thus disproving Ender's claims for concentration, since his product showed no bands in the ultra-violet. Brockmann argues that Ender's claims must have been overstated by 900 per cent! In other words, that his preparation cannot have contained as much as 10 per cent of the vitamin and cannot have had more than one tenth of the biological activity claimed by him.

The constitution of this vitamin, for which Brockmann proposes the symbol D_3, would not be known but for the brilliant parallel investigations of Windaus, Schenck and Werder, whose results are published alongside Brockmann's. It is now rather more than a year since Windaus, Lettré and Schenck announced the preparation of 7-dehydro-cholesterol ($\Delta^{5,6;\,7,8}$ cholestadien-3-ol) and stated that it could be made antirachitic by irradiation. They have now isolated the crystalline 3,5 dinitrobenzoate of the active irradiation product, as well as its colourless non-crystalline hydrolytic product. Both appear to be in every respect identical with the corresponding substances prepared from tunny-liver oil. It would therefore seem almost beyond doubt that, since 7-dehydro-cholesterol has formula III, the tunny-liver vitamin must be constituted as shown in IV.

---

* *Hoppe-Seyler's Zeitschrift für physiologische Chemie*, **241**, 100, 104, 116, 125, 129 (1936).



III

If this formula correctly represents the constitution of vitamin D_3, it differs from calciferol only in the absence of the double bond at the side-chain position $C_{22}=C_{23}$, and the replacement of the terminal side-chain group $—CH(CH_3)—CH(CH_3)_2$ in calciferol by $—CH_2—CH(CH_3)_2$ in vitamin D_3. The physiological differences between the two vitamins must be determined by the differences in the two side-chains which are shown here alongside.

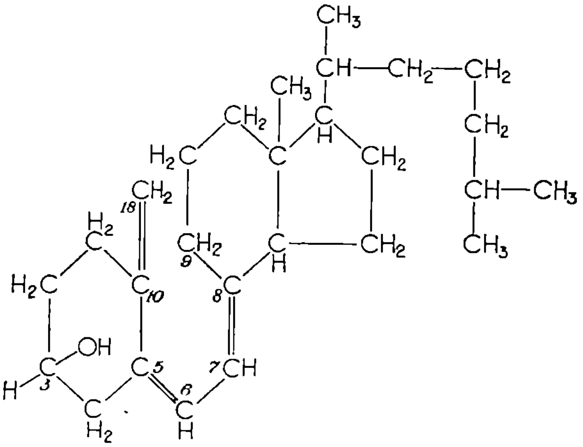
$—CH(CH_3)—CH=CH—CH(CH_3)—CH(CH_3)_2$
Calciferol

$—CH(CH_3)—CH_2—CH_2—CH_2—CH(CH_3)_2$
Vitamin D_3

This is in itself a quite remarkable finding, but it becomes a mystery when we consider two further investigations reported simultaneously with those summarized above. Wünderlich has prepared 7-dehydrositosterol and irradiated it. The crude irradiation product appears to have only about one fortieth of the antirachitic potency found in irradiated ergosterol, produced presumably under identical conditions. It is not, however, legitimate to argue that the isolated vitamin will have one fortieth the activity of calciferol, since the relative amounts in the two crude irradiation products may be different. If, however, the general course of the photochemical changes is identical, then the vitamin from dehydrositosterol must differ from calciferol and vitamin D_3 only in the structure of the side-chain, which is

$—CH(CH_3)—CH_2—CH_2—CH(C_2H_5)—CH(CH_3)_2$
(Sitosterol)

There is, in fact, a replacement by an ethyl group of one hydrogen atom on carbon atom C_{24} in the side-chain of cholesterol. From the above data it would appear as if the $C_{22}=C_{23}$ double bond in calciferol were responsible for its exceptionally potent effect on rachitic rats, compared with that on chickens, and this is borne out by the fact that the irradiation product of 22-dihydroergosterol has been reported by Windaus and Langer as having only one thirtieth the activity of irradiated ergosterol. Here again, however, it must be emphasized that crude irradiation products, not distin[illegible] crystalline compounds, were being compared. The low activity of irradiated 7-dehydrositosterol may, therefore, be due either to the absence of the $C_{22}=C_{23}$ double bond, or to the extra carbon atoms in the side-chain, or to both.



IV

The greatest puzzle, however, arises from a study of 7-dehydrostigmasterol, prepared and irradiated by Linsert. The side-chain of stigmasterol, and therefore presumably of 7-dehydrostigmasterol and its active irradiation product, is

$—CH(CH_3)—CH=CH—CH(C_2H_5)—CH(CH_3)_2$
(Stigmasterol)

Here we have the $C_{22}=C_{23}$ double bond associated with the activity of calciferol, and the simple replacement of the ergosterol methyl group at C_{24} by an ethyl group. According to Linsert, the irradiation product of 7-dehydrostigmasterol is "überraschenderweise" nearly or entirely without any antirachitic action! Yet it is chemically, to all appearances, much more akin to calciferol than any of the other products discussed in this article. Moreover, if 22-dihydroergosterol gives an irradiation product that is very active, though markedly less so than ergosterol, it is inexplicable that 22-dihydro-7-dehydrostigmasterol, which is in fact 7-dehydrositosterol, should give a *more* antirachitic irradiation product than the stigmasterol derivative.

The facts relating the side-chain constitution to the antirachitic properties of their irradiation product can be summarized thus:

Sterol	Carbon atoms in side chain	Double bond in side chain	Antirachitic potency
Dehydrocholesterol	8	0	++++
Ergosterol	9	1	++++
Dihydroergosterol	9	0	+++
Dehydrostigmasterol	10	1	?
Dihydrodehydrostigmasterol (Dehydrositosterol)	10	0	+

It has been suggested by Schoenheimer that the number of carbon atoms in the side-chain has a profound effect on the absorbability of sterols. If this be so, and if it apply also to the irradiation products, the explanation of the facts cited may be found along these lines. Difficulty in accepting such an explanation, however, arises from the fact that ergosterol shows, like sitosterol and other plant sterols, poor absorbability, while cholesterol is very well absorbed, yet the irradiation product of ergosterol is apparently absorbed as easily as that of dehydrocholesterol.

The various papers here summarized are supplemented in the same journal by a very interesting account, from Brockmann and Chen, of an antimony trichloride colour-test for both vitamin D_3 and calciferol. The authors claim a considerable degree of specificity for the test, and it will doubtless be eagerly tried by many workers in this field.

A. L. BACHARACH.

British Regional Geology

IN the new Museum of the Geological Survey at South Kensington the exhibition of British geology has been arranged on the basis of a division of the country into eighteen districts, each of which forms a geological and geographical province of distinctive type. To each region a separate division of the main floor or first gallery has been assigned, and in order to render the exhibits more intelligible descriptive handbooks have been prepared to serve as guides. These handbooks, issued under the general title of "British Regional Geology", also serve as compendious summaries of local geology. Eleven have already been published and these are briefly noticed below.

The Survey is to be warmly congratulated on the success of this important new enterprise. Each handbook is beautifully illustrated with maps, diagrams and plates, and the descriptive matter adequately provides all the necessary detail for a general comprehension of the area concerned. The complete series will constitute the most authoritative and attractive account of British geology as a whole which has ever appeared; one, indeed, that will be indispensable to students for purposes of general study. The individual numbers, issued at the remarkably low price of 1*s.* 6*d.* each, serve as welcome introductions to the more specialized sheet memoirs, and also as guides to tourists and others who wish to appreciate the interest and significance of the geological features of any British district.

"London and Thames Valley"[1] embraces a region from Oxfordshire and north Wilts to Essex and north Kent. It thus comprises beds ranging in age from Lias to Pleistocene and Recent, the main features being the Chalk escarpment of the Chiltern Hills and its continuation west of the Goring Gap, and the middle of the London Basin. Palæozoic formations are known from numerous borings, most of the rocks bearing a general resemblance to those of the Welsh Borders. As in most of the other handbooks of the series, an excellent list of maps and memoirs and a selected bibliography of other publications dealing with the district are appended.

The handbook on "The Wealden District"[2] covers the area to the south of the above and is probably one of the most familiar geological regions in the world. The Weald proper is continued across the Straits of Dover into the Bas Boulonnais. Beds of many ages are concealed beneath the covering of surface rocks, and at the eastern end of the Weald every system of older stratified rocks from the Silurian upwards is represented, although the complete sequence recognized has not been found in any one boring. A very clear diagrammatic section is given showing the active collieries and working seams of the Kent Coalfield. Water, however, is fundamentally the most important of the economic resources of the Wealden District, since practically all that is used is derived from underground sources.

"Bristol and Gloucester District"[3] extends from the Forest of Dean across the Severn to the Cotteswold and Mendip Hills. Geologically speaking, it is one of the most varied districts of Britain, for, with the exception of the Ordovician and possibly the Permian, there is exposed at the surface every geological formation from the Cambrian to the Cretaceous. Scenically, some of the most striking features, including caverns, gorges and bare rocky crags and uplands, are developed from the Carboniferous Limestone. On the west, limestones again dominate the scenery, the Inferior and Great Oolites forming the mural scarp of the Cotteswolds. These great limestone formations have attracted many famous geologists, the names of Arthur Vaughan and S. S. Buckman being pre-eminent as a result of their classic work on zoning. Tectonically, the synclinal areas of the Bristol, Somerset and Forest of Dean Coalfields and the echeloned periclines of the Mendips are of special interest.

"South-West England"[4] is a region of high moorlands, including the Devonian rocks of Exmoor and the Quantocks, and the granite masses from Dartmoor to Land's End and the Scilly Isles. At the base of the geological sequence lie the Pre-Cambrian rocks of the Lizard and Start Point. In 1834, De la Beche had already produced a geological map of Devon which led to his appointment as the first Director of the newly established Survey. Since then the region has been famous not only for the pioneer investigations of its mineral wealth, but also for the many contributions it has stimulated to our knowledge of petrology generally, culminating in the work of Teall, Flett, Dewey, and, still more recently, of Brammall and his school of co-workers. This handbook is itself a most valuable introduction to a great variety of petrological problems and there is, moreover, a most interesting section on mines and mining.

The handbook entitled "The Welsh Borderland"[5] covers a region from Shrewsbury to south of Monmouth. It includes such geologically classic areas as the Wrekin, the Longmynd and the Malverns, where some of the most ancient rocks of England and Wales appear boldly at the surface; the Stiperstones and Shelve country and the Breidden Hills, where Ordovician rocks are magnificently displayed; and Wenlock Edge, famous in the sequence of the Silurian System which was first established by Murchison in 1835 as a result of his work in the Welsh Borderland. Much of the modern research in the region was initiated by Lapworth and Watts, whose stimulating example has been vigorously followed by a host of colleagues and former students. Indeed, many geologists have received their field-training in this area, which is unrivalled for the great variety and interest of its formations, many of which, moreover, are highly fossiliferous. The present handbook provides an invaluable guide to the classes who annually visit Shropshire and the country about the Malverns for instruction in field-geology.

Another classical region in the history of geology is dealt with in "North Wales"[6]. Here Sedgwick set himself the task of disentangling the structure of the rugged mountain district of Snowdonia and Lleyn, and here he founded the Cambrian System. Since then North Wales has attracted to its study an ever-growing band of stratigraphers, palæontologists and petrologists. The region is essentially characterized by Lower Palæozoic rocks, displaying one of the finest sequences of Cambrian, Ordovician and Silurian strata to be found in Europe; showing by deep-seated erosion the cores of ancient volcanoes; and revealing in its crumpled, folded, cleaved and fractured sediments the record of several periods of major earth-movements. Of the remaining systems, the underlying Pre-Cambrian is well represented in Anglesey, while the Carboniferous and New Red Sandstone cover fairly extensive tracts on the borders. Like the foregoing, this handbook will be in great demand by students attending geological field-courses.

"The Pennines and Adjacent Areas"[7] include the Fell country from Stainmore Pass to the Craven district, consisting mainly of Carboniferous Limestone; the Central Pennines between Skipton and the Peak, largely formed of the Millstone Grits (and shales); the Derbyshire Hills of Carboniferous Limestone; the Lancashire and North Staffordshire Coalfield on the west; and, on the east, the coalfield of York, Derby and Nottingham which, in potential resources, is the most important in Britain. The great diversity of geological and physical features is accompanied by an even greater variety of economic interest and by a corresponding inequality in the distribution of population. The oldest rocks in the region—apart from the supposed Pre-Cambrian of Ingleton—are the Lower Palæozoic formations exposed in the valleys below Ingleborough and in the Howgill Fells. The interest of the coalfields needs no stressing, but geologists will particularly appreciate the useful summary of the structure of the region and the excellent account of the Pleistocene glaciation.

Northumberland, Durham, the Lake District and the Isle of Man are dealt with in "Northern England"[8]. The Northern Pennines continue to the Border and separate a great coalfield on the east from the most attractive scenic area of England, an area which is itself fringed with coal and iron fields. The formations range from the Ordovician to the Jurassic and include a long history of igneous activity, the products of which are responsible for the rugged hills of Borrowdale; the worn-down volcano of the Cheviots; the well-known granites and Carrock Fell complex of the Lake District; the Great Whin Sill, surmounted for a considerable length of its outcrop by the Roman Wall; and a swarm of dykes which has been traced across Scotland to the Tertiary volcano of Mull. Along the Durham coast, the Magnesian Limestone of the Permian System constitutes one of the most puzzling formations—lithologically and structurally—to be found anywhere in the world. The results of much recent work in the Lake District have been incorporated in the handbook, but in a future revision more attention might be given to the North Pennine ore-deposits and to the Tertiary dykes, or at least to the desirability of including bibliographical references to these subjects of recent research.

"The South of Scotland"[9] is devoted to the region between the Cheviots and Solway Firth on one hand, and the faulted southern margin of the Midland Valley on the other. Here some of the fundamental principles of geology were established by Hutton and recorded in his "Theory of the Earth" (1795). It was in the Southern Uplands, too, that Lapworth began the far-reaching studies in which he demonstrated the value of graptolites as aids in working out the complicated succession and structure of a highly folded region. The area is mainly occupied by Ordovician and Silurian strata folded in part after the Arenig and, as a whole, at the close of the Silurian. The intrusions of serpentine and other plutonic rocks which have usually been regarded as pre-Glenkiln are considered by Dr. Pringle to be part of the Pre-Cambrian floor on which the Arenig strata were deposited. Small areas of Old Red Sandstone, Carboniferous and New Red Sandstone occur, with abundant illustrations of igneous activity in the great granite complexes of Galloway and the volcanic rocks and necks of Lower Carboniferous age. This handbook, like the one that follows, has a selected bibliography after each section, in some respects a preferable arrangement to placing the whole at the end. The map of the region, showing many localities of geological interest not easily found on detailed maps, is particularly clear.

"The Grampian Highlands"[10] embraces the region between the Highland Boundary Fault and the Great Glen Fault. It excludes Arran, but is extended to take in Colonsay. The two fault lines represent great dislocations along which movements are still taking place, as witnessed by the earthquakes which occur about Inverness and Comrie. The district includes the highest ground in Britain and is geologically by far the most difficult on account of the inexplicable complexity of its structure. The most important formations are those of the Moine and Dalradian divisions of the Highland Schists. A particularly valuable feature of the handbook is the clear summary which it contains of the different interpretations of succession and structure which have been proposed; this is the more useful because, as the author says, "it will doubtless appear to the reader that there are as many opinions as observers". The treatment of the igneous rocks earlier than, or associated with, the Dalradian metamorphism, and that of the Newer, or Caledonian, intrusions is also worthy of special praise. All students of tectonics and petrology will find this handbook a most helpful guide to a region of tantalizing perplexity.

Under the title "Scotland: The Tertiary Volcanic Districts"[11] the magnificent record now exposed in the west of Scotland, of the intense and prolonged igneous activity which broke out in Early Tertiary times, is discussed. The vast amount of denudation which has since taken place has revealed the extensive roots of mighty volcanoes and the deeper-seated plutonic rocks that crystallized beneath the covering of lavas. The complexity of the vents and intrusions and the orderliness of the ring-structures (ring-dykes and cone-sheets) are unsurpassed in any other part of the world. Only brief accounts of the pre-Mesozoic formations are given, the bulk of the handbook being devoted, as its title indicates, to (*a*) the plateau lavas; (*b*) the Central Intrusion complexes of Mull, Ardnamurchan, Skye, Rum, St. Kilda and Arran; and (*c*) the dyke-swarms. This justly famous petrographic province has stimulated world-wide discussion of problems of petrogenesis. In this connexion it may be pointed out that the official interpretation of the upward passage of gabbro into granophyre in the ring-dykes of Mull as the result of gravitational differentiation *in situ* has not remained unchallenged. The handbook is lavishly illustrated and, at least for petrologists, it may be hailed as the most attractive example of a series that is a worthy commemoration of a hundred years of geological research in Britain.

Obituary

Lieutenant-General Sir Alfred Keogh, G.C.V.O., G.C.B., C.H.

IT can scarcely be doubted that, by coming generations, the Great War will be held to mark an epoch in the history of medicine. Taking medicine in its widest sense, as a calling centred on the preservation of life and the mitigation of human suffering, its historian will have to go back to the day of Lister for anything comparable to the rapid and marvellous advance that was made during the War. The two cases are certainly widely different. Lister, like Pasteur, stands in solitary grandeur on the plains of peace, conferring after laborious days the splendid and enduring gift which his rare genius had put into his hands to bestow. In the case of the War, many great names are involved—it was team-work on a titanic scale. No one man among them stands as Lister stood among his fellow labourers. But moving about among the soldier and civilian members of the medical profession who are most competent to judge, the impression is left that if a name were to be chosen for the seat of honour, none could come before that of Sir Alfred Keogh, whose death at the age of seventy-nine years occurred on July 30.

Of talent of almost every kind, the Briton, like the men of other nations, is apt to say we have no lack; but in the art of fostering talent, of affording it the best field for action, of bringing it into focus on the things that are of most vital concern to the nation, the Briton is much less inclined to boast. Of the master art of the harmonious control of gifted men, it is still less the case. Here indeed lies the loudest complaint to-day about the expiring generation, and here also arises the haste to organize, systematize, rationalize, and almost, if one may be permitted to say, to 'Germanize' our ways. According to the adage, "It is lawful to learn from the enemy; it is both wise and lawful to learn from a friend who may also be a potential enemy". This in the Great War meant that Lord Haldane, when Minister of War, had embodied in the administration of the army sufficient of the ways of the German General Staff to help him in securing that six divisions were ready for instant embarkation to the field of war in August 1914, going at once into action. This, according to Earl Haig, was the foundation of victory.

Sir Alfred Keogh's appointment as Director-General of the Army Medical Services was almost simultaneous with that of Lord Haldane as Minister of War. It would, perhaps, be adding too much in praise of Lord Haldane to say that he had at once taken the full measure of the man whose appointment was to mean so much. Suffice it to say, that in Sir Alfred Keogh there was embodied all that was best in the ways of the German General Staff and all that was best in the military traditions of our own country. He was, however, not an imitator, but a man in whom great powers of initiation were inborn.

It would be out of place here, and beyond the writer's power, to give in any detail the record of Sir Alfred Keogh's work in the army. Its essential character can only be briefly indicated. In the first place, the imagination of Keogh, like that of his illustrious fellow countryman Earl Roberts, had enabled him to foresee in wonderful degree the conditions which would obtain in Great Britain in the event of foreign war. He foresaw its magnitude, and the scale of preparation that was required. On the formation of the Territorial Army, under Haldane's regime, Keogh laid, along with it, the foundation of a vast voluntary civilian medical service, which at the outbreak of war sprang into action, appearing with its great military hospitals, staffed with men of the highest medical skill, and the countless number of voluntary aid detachments, with their minor hospitals and training centres. He blended the civilian medical profession and the Army medical service and effected a perfect liaison between the organizations in the field and the organizations at home. It is confidently stated that no other army had its like in the efficiency of its medical service. How many thousands are there to-day, alive; how many thousands are there repaired, who in the conditions of any preceding war would have perished, or been left with grave injuries of kinds which gr to be remediable during the Great War ?

The Army Medical Services were not prepared for everything. Among the unforeseen conditions of war in the field, no more conspicuous case could be cited than that of the outbreak of gas warfare. If foreseen as a possibility by Keogh, he, like other soldiers, regarded its incidence as so unlikely that he had no measures of defensive protection designed or in readiness. The results of this, if ever revealed in detail, would serve like the exception that proves the rule to show how much danger must have been entailed by any gap in Keogh's prevision and provision. He did all he could on the spur of the moment amid the toils of hard labour, to meet the new peril, and happily the co-operation of another born leader of men, Sir Henry Thuillier, brought the protection of troops against gas in advance of the attack, and kept it so up to the end of the War.

Keogh was ever ready to listen to proposals that came from people whom he could trust. He assumed no pontifical air; he was rather the supreme and vigilant officer, under whose direction the collected legions of the profession, and the collected outcome of medical investigation at home, passed without delay to wherever lay the appointed place in the field of war.

Turning now to the other field in which Keogh worked, we might stop to say much on the position of medicine in relation to experimental science. It might well be contended that Keogh in his Great War work exhibited the scientific method. He certainly had imagination, a real love of science, and far more of real science in him than most medical men. If he is not strictly to be regarded a man of science, at least he believed in science wholeheartedly, and knew its ways. This gave him one great qualification for an administrative scientific post, and when we add to this his administrative achievements, as D.G.A.M.S. before the War, we cannot wonder that Lord Haldane, best aware of them, urged in 1910 the appointment of Keogh to the rectorship of the Imperial College of Science, which at that time, above all things, needed a talented administrator at its head. This post Keogh held actively from 1910 until 1914, when he was recalled to his old position at the War Office.

After the War, Keogh returned to it eagerly, and retired reluctantly from it only when he reached the age of sixty-five years in 1922. How much he loved the work can be gauged from the fact that at the most critical period of the War he said, with a rueful smile to the writer, that he was longing "to get back to South Kensington". Many readers of NATURE will have personal recollections of Keogh at the Imperial College. They may, perhaps, be puzzled to pick out any conspicuous act of reorganization likely, outside the College, to be associated with his name. If those who had the happiness of holding teaching or other office at the College during his rectorship are asked what he did, they too cannot, or will scarcely stop to tell you. For all thoughts of what he did are overwhelmed by the thought of what he *was*.

Keogh was above all else a veritable knight, a Christian Irish Catholic gentleman, endowed with all the graces that these words imply, not forgetting the savouring salt of humour. No wonder he was so much beloved by those who were nearest to him, and honoured and respected by those further removed who came into contact with him. By his War work he earned his place among the greatest who have served mankind, and incidentally to the work, he stood a noble figure bent on the advancement and right use of natural science. A. S.

Mr. R. R. Webb

ROBERT RUMSEY WEBB, the last of the famous coaches for the old Mathematical Tripos, died in Cambridge on July 29, at the age of eighty-six years. He was born at Monmouth on July 9, 1850 and went up to St. John's College, Cambridge, in 1868 as a sizar. In 1870 he was admitted a scholar of the College; in 1872 he was Senior Wrangler and first Smith's Prizeman. His election to a fellowship followed immediately; in 1878 he was appointed College lecturer in mathematics, holding this post until 1911; from 1878 until 1893 he was also lecturer at Emmanuel College. He retained his fellowship until his death, and he lived in rooms in College until a few years ago, when he moved to the house of his former 'gyp'.

From the date of his degree, Webb devoted his energies to training pupils for the competitive struggle of the Tripos. He was one of the famous line of coaches which included Hopkins, Routh and Besant; he worked his men hard, but, as the letters which appeared in *The Times* after his death testify, he inspired and retained their affection, as well as their admiration for the masterly way in which he could manipulate such things as 'moving axes' in rigid dynamics and differential geometry. Naturally, in later days, after he had given up dining in Hall, for reasons variously reported, he became somewhat of a legendary figure. For example, the story was told that, in term time, after a strenuous morning's teaching, it was his invariable practice to go by train to Royston and walk the thirteen miles back to Cambridge, arriving so precisely at the same time each day that the College porters set their clock by him.

Webb did not take a great share in University business, though to the end of his life he was keenly interested in what was going on and, even in his seclusion, he always seemed to know the latest gossip. He examined four times for the Mathematical Tripos; the present Vice-Chancellor of the University recalls how hard he was made to work solving Webb's problems, and how much mathematics he learnt, when he was a co-examiner in 1905 and 1906.

Webb's published work is small in volume, but he was always interested in the progress of mathematics, and kept in touch with many of its developments, even after his retirement; his rooms were crowded with mathematical periodicals and treatises, as well as with paper-backed novels, in French and other languages. He had been a member of the London Mathematical Society since 1873 and he certainly attended one meeting, in January 1878, when the minutes record that "Prof. Cayley gave an expression for the surface of an ellipsoid which had been communicated to him by Prof. Tait", and "Mr. Webb made a few remarks upon the subject". On this occasion, Webb was persuaded to print his own version, and the result is "Some Applications of a Theorem in Solid Geometry" (*Messenger of Math.*, 9, 170; 1880), one of eight papers appearing under his name in the *Messenger*, vols. 9–11, the most considerable of which deal with dynamics and elasticity. He also published a paper on attractions in the *Quarterly Journal* (14, 98; 1877), and communicated in 1886 a short note "On the Problem of Three Moments" to the Cambridge Philosophical Society (*Proc.*, 6, 42; 1889). But he never could be persuaded to work up into a book any of his numerous manuscripts, which he was so generous in lending.

WE regret to announce the following deaths:

Prof. Henry Sewall, emeritus professor of medicine in the University of Colorado, an authority on human physiology and tuberculosis, on July 8, aged eighty-one years.

Mr. C. F. Talman, meteorologist in the U.S. Weather Bureau since 1922, on July 24, aged sixty-one years.

Prof. Frédéric Wallerant, formerly professor of mineralogy in the University of Paris, aged seventy-eight years.

News and Views

Television in the Home

On the occasion of the opening of the Radio Exhibition, referred to on p. 410 of this issue, on August 26, an opportunity was provided by Messrs. Baird Television, Ltd., of witnessing the reception of the television programme broadcast from the B.B.C. station at Alexandra Palace. The demonstration was given on a standard Baird Televisor receiving set installed in the company's offices in Haymarket, under conditions which approximated to reception in the home. The receiving set was contained in a cabinet similar to the ordinary radio-gramophone, the picture on the screen of the cathode ray tube being viewed in a mirror in the raised lid of the cabinet. This picture was of such dimensions and height that it was comfortably visible by the viewer seated on a settee at a distance of about ten feet. The transmissions from the Alexandra Palace are, of course, only experimental; but the direct-vision pictures provided, including half or three-quarter length views of single persons, such as the announcer and a singer, were very satisfactory. The bulk of the programme, however, comprised the transmission of sound films, and while these were good on the whole, they emphasized the somewhat limited field of the vision picture by a loss of detail when this picture covered a large area or a crowd of persons. As an indication of the present-day possibilities of practical radio-television, however, this demonstration was most successful.

Dr. J. H. Hutton

It is announced that Dr. John Henry Hutton has been appointed a lecturer in the Faculty of Archæology and Anthropology in the University of Cambridge, for a period of three years as from October 1. When the intention to appoint a lecturer in this Faculty was notified in the course of last term, it was intimated that a special knowledge of the peoples of India would be a requirement. In this respect, Dr. Hutton's qualifications are beyond question. As a member of the Indian Civil Service, which he entered in 1909 after taking his degree at Worcester College, Oxford, Dr. Hutton has made a special study of the ethnography of the Nagas of Assam. Not only is he himself the author of two of the volumes in the series of monographs published under the auspices of the Government of Assam, one dealing with the Angami Nagas (1921) and the other with the Sema Nagas (1922), as well as a contributor of numerous papers on Naga culture to scientific periodicals, but he has also so stimulated and organized the researches of his colleagues that the hill tribes of Assam are now as well, or even better known to anthropological science than any other comparable population of India. When Dr. Hutton was seconded under the Government of India to take charge of the Census of India, 1931, it was generally felt that no more suitable selection could have been made. His introduction to the Report marked him as no unworthy successor to the late Sir Herbert Risley. However much opinions may differ as to the validity of the conclusions on the racial history of India at which Dr. Hutton arrived in that remarkable document, it cannot be denied that he has shown a notable breadth of outlook in grasping the essentials of his problem in their archæological and historical perspective, combined with a detailed knowledge of the multifarious facts, which is without rival in the Indian field.

Economic and Military Armaments

In the eighth Richard Cobden Lecture entitled "The Common Menace of Economic and Military Armaments" delivered on May 25 and now published (Cobden-Sanderson, Ltd., 1*s*. net), Prof. W. E. Rappard, discussing the relations between economic and military armaments, points out that as military armaments have contributed to the development of economic armaments, so the latter in turn have promoted the extension of military armaments by emphasizing the claims of the national State as against the rights of the individual and of mankind, and thereby increasing the tension in international relations. Both economic and military armaments are largely the legacy of past wars or the fruit of anticipation of future wars. Their primary source, however, is the doctrine of political nationalism which leads nations to look upon their own State as a universe in itself and therefore to disregard the rights of all others. A further source is in the present depression and in the efforts to overcome it by thorough-going State intervention.

Both economic and military armaments are weapons forged to enhance the independence, security and power of the national State. While a burden to the individual and a menace to the international community, they are incapable even at this price of truly fulfilling their professed purposes, and the present international situation must inevitably be aggravated by a persistent adhesion to these methods. Discussing the difficulties due to the existence to-day of at least three Great Powers of professedly and defiantly nationalistic Governments, Prof. Rappard suggests that the problem of international peace resolves itself into one of national ideals and conversions. Unless these nations can be led to adopt a more humane and less exclusive creed, peace can only be maintained by the closest co-operation between all those States, which, while respecting their own as well as their neighbours' statehood, still believe in the legitimate rights of the individual and in the supreme rights of mankind. Without a federal organization of the international community, there can be no real liberty, no lasting peace and no true relief from economic and military armaments.

Maiden Castle, Dorchester

THE most striking point to emerge from this season's excavations at Maiden Castle, so far as they have gone, is the conclusive evidence confirming Dr. Mortimer Wheeler's inferences as to the importance of the pre-Roman fortress-settlement in Britain. Should further investigation confirm his views as to its prevalence as an organized system, this should have a profound effect on theory as to the origins and form of town life in early and medieval England. The importance of Maiden Castle itself may be gauged from the evidence now being found of the deliberate destruction of the walled system of defences when the inhabitants were removed in Roman times to the newly founded neighbouring city of Dorchester. As investigation proceeds, the character of the prehistoric stone walling, which has now been found incorporated in the ramparts, and of which the existence was previously unsuspected, becomes more and more impressive. These walls were built of limestone from Upwey, some of the blocks weighing as much as five hundredweight. At the eastern entrance a later wall of fine masonry now being uncovered still stands to a height of six courses. Not only is it evident that it overlies earlier prehistoric levels of occupation, but it is also clear that it was designed to form a blocking wall across the prehistoric gateway when the hill-top temple was being built in the century preceding the coming of the Romans. Within the fortress itself, the remains of a substantial structure of wood, standing at the highest point of the camp, is being excavated. This was evidently of considerable size, and was in part constructed of tree-trunks a foot in diameter. Nearby a skeleton was found buried at some depth, an unusual feature in a fortress. The excavations will be continued until the end of the present month, when the three years' investigation which was undertaken by the Society of Antiquaries of London with the co-operation of the Dorset Natural History and Archæological Society will have been completed.

Meare Lake Village

EXCAVATIONS at Meare Lake Village have been resumed by the Somerset Archæological Society under the direction of Dr. Arthur Bulleid, and will continue until at least the middle of September. According to a preliminary report in *The Times* of August 29, the stone walling overlying the timber structure, apparently the foundations of a crannog, found last year in the central part of the eastern half of the village, is being examined further. The eastern margin and the south-eastern and north-eastern portions are now in course of investigation. Work has also been begun on the southern border of the village outside a definite dwelling. Timber and oak piles are being revealed, and in a layer of black earth a number of small finds have been made, which include a La Tène III brooch, a few objects of bronze, an antler weaving comb, a 'pygmy' pottery vessel, and a small Romano-British pot of the type known as 'Cossington' ware.

im Thurn Memorial Lecture, 1936

IN the recent lecture for 1936 on the foundation in memory of the late Sir Everard im Thurn, delivered at Edinburgh, Prof. J. L. Myres directed attention to the effect of changing outlook and development in method of research on the broader philosophic principles, which underlay the work of im Thurn. To the study of primitive peoples he conjoined the application of its results to the practical problem of the approach to the primitive mind in administrative and other affairs. He realized that this problem was but the counterpart of any native's difficulty in understanding European ways. im Thurn, Prof. Myres pointed out, insisted on the significance of 'character' which, whatever the superficial changes in culture, continues to influence native reactions to 'civilization'. This 'civilization' was defined as that in which "the prime motive of human action was the good of others or of one's whole race". As regards 'character' and 'culture' and their interaction, all grades between the individual completely disciplined by 'culture' and the man of genius can be discerned.

SINCE im Thurn's day, advance in scientific method has shown that culture and character alike appear as a composite system, or complex of elements, combined in different peoples in infinitely varying degrees of intensity. In a society in which transitions from one phase of life and society are effected mainly by individuals in isolation, character and initiative stand high, and in that society institutions are relatively unstable. Where, however, the rites of transition are matters of public concern and are performed by whole groups of initiates, behaviour and social structure are stabilized, character is stereotyped, originality suppressed and stagnation ensues. Our knowledge of 'primitive' cultures is mainly derived from such societies. Out of such closed cultures what way of escape is there, Prof. Myres asked. How does what im Thurn defined as civilization emerge as an altruistic prime motive of human action ? Prof. Myres illustrated from the history of ancient Egypt, early Greece and elsewhere how in fact such transformations do take place, though they do not preclude the apparition of a dominant individual character as first cause, and they presume elementary freedom to choose the well-being of others, once presented as the prime motive of human action.

Bibliography of Natural History

THE first general meeting of the Society for the Bibliography of Natural History was held in the rooms of the Royal Entomological Society on August 26. The provisional committee set up to establish the Society made a report and submitted draft by-laws which were accepted as the by-laws of the Society. The following officers were elected : President : Dr. C. Davies Sherborn ; Treasurer : Mr. Francis Hemming ; Secretary : Mr. Francis J. Griffin ; and a committee of management set up consisting of Prof. F. Balfour-Browne, Mr. J. R. Norman, Mr. J. Ramsbottom, Dr. T. A. Sprague and Mr. A. Cockburn Townsend. It was announced that the first part of the Society's *Journal* would appear in September, and that it would contain a catalogue of all known papers giving information relating to the dates of publication of books on natural history. No such catalogue at present exists, and the publication should be of value to all systematists. An item on the programme of the Society which it is hoped will be of great value to all naturalists is the publication of facsimiles of rare works of importance to natural history. The decision of the Society to maintain an information bureau for the use of its members is an indication of the present trend of societies to make available to the individual member the collective experience and knowledge of all. The annual general meeting of the Society will be held on the first Saturday in February.

International Botanical Congresses

A FEATURE of the sixth International Botanical Congress held at Amsterdam last September was the re-organization of the Botanical Section of the International Union of Biological Sciences and its recognition by the Congress as a liaison between successive International Congresses. Hitherto, each quinquennial congress has been independent of preceding congresses, and has been organized entirely by an *ad hoc* committee of the nation which was acting as host. Participation by other nationals in its various activities was by invitation. A drawback of this arrangement has been the absence of any body to ensure that resolutions passed by one congress were carried out and that committees appointed for definite objects were set to work. A circular has now been issued by the honorary secretary of the Botanical Section of the Union describing the aims of international collaboration in science in general, and in particular defining the work of the Botanical Section in relation to successive congresses. The circular emphasizes the independence of the quinquennial congresses, the organization of which remains entirely in the hands of a national committee; but the various commissions and committees appointed by successive congresses will be adopted by the Botanical Section of the Union and thus "be united into a permanent, active and well-subsidized organization". This should ensure that work initiated at any one congress will be effectively carried out. For the present a definite liaison is suggested between the two organizations as the president of the Botanical Section of the Union, Prof. N. E. Svedelius, is vice-president of the next International Congress to be held in Stockholm in 1940. The president of the Congress is Prof. R. E. Fries.

Forestry Research in Canada

As a result of recommendations made at a Conference on Forestry Research held in Ottawa in November 1935, the National Research Council of Canada has appointed a committee to study the requirements in respect to research in all branches of forestry, including measures for the better utilization of forest products. This committee is to function as an associate committee of the National Research Council, and includes in its membership representatives of the Dominion Departments of the Interior and Agriculture, in addition to the National Research Council; the forestry departments of each province; members of the forestry faculties of universities in which there are departments of forestry; the lumber, pulp and paper and allied industries throughout the Dominion; the forest engineering societies; the forest protective associations and the Canadian Forestry Association. It is understood that the committee will base its preliminary programme on the findings of the Conference on Forestry Research held in November 1935 already alluded to. The importance of forestry and her forests to Canada needs no emphasizing. Much valuable work is being done already in the direction of research by federal and provincial agencies, individual companies and other organizations. The new committee will bring together data on the work at present in progress, correlate the information thus obtained, investigate the need for further research, and so forth. It is evidence of broad and statesman-like views among those responsible for the formation of the committee that representatives of all sides of forestry interests are included. In Great Britain, the position is far otherwise—research work is too often relegated to water-tight compartments, energies being thus dissipated; forestry committees are not fully representative of all sides of forestry; whilst representatives of the individual forestry staffs of the universities as a whole do not automatically find places on forestry research committees.

Control of Rabbit Infestation by the Use of a Virus

OF all the pests from which the pastoral industry in Australia has suffered, rabbit infestation is probably the most serious economically, and little permanent success seems to follow the methods of control in use at present, such as trapping and poisoning. One hope would appear to lie in the discovery of some infectious disease, deadly to the rabbit but innocuous to man and other animals, and easily communicable to, and spreading widely by natural means among, the rabbits. Sir Charles Martin, as a result of an experimental inquiry, suggests that a disease 'rabbit myxomatosis' may fulfil these requirements (Commonwealth of Australia. Council for Scientific and Industrial Research, *Bull.* No. 96. Melbourne, 1936). This is an infectious, highly fatal, febrile disease caused by an ultra-microscopic virus, causing mucinous discharges, swellings and tumours in affected animals, fatal within twelve days or so, transmitted sufficiently by contact, and with a fatality of almost a hundred per cent. It attacks animals of the genus *Oryctolagus*, to which wild rabbits in Europe and Australia, and domesticated rabbits in Europe and America, belong; but it does not affect the indigenous rabbits of America, or man and other animals and birds. Experiments were conducted by Sir Charles Martin in a pen measuring 50 yards × 10 yards, with both tame and wild rabbits. A colony having been established for three weeks or thereabouts, one or two rabbits inoculated with the disease were introduced. With colonies of 27 and 30 tame, and 55 and 44 wild, rabbits, the fatality was 99·6 per cent among the tame, and 100 per cent among the wild. The disease originally came from epizootics among tame rabbits in South America.

Research at Millport

THE Annual Report of the Executive to the Council of the Scottish Marine Biological Association for 1934–35 includes the director's report on research. Drs. Orr, Marshall and Nicholls are concentrating on the development and food of the herring from hatching onward. In this connexion, it is found that copepods are by far the most important food organisms, the larval and post-larval herring eating chiefly the small species. In view of this fact, it was decided to investigate seasonal distribution and breeding periods of these small copepods, in the same way as has already been done for *Calanus finmarchicus*. Results so far show that in the early months *Microcalanus pusillus* and *Oithona helgolandica* were the most abundant species, with *Pseudocalanus elongatus*, *Centropages hamatus*, *Temora longicornis* and *Acartia clausi* occurring in smaller numbers. Most of the important planktonic organisms have been weighed, and in some cases the chemical composition determined. During the winter, when zooplanktonic organisms are scarce, a beginning was made on the analysis of non-planktonic animals important as fish food. Investigations on shore ecology, especially in Kames Bay, by Dr. A. C. Stephen and Mr. Elmhirst, have been continued. The work already done has shown a very rich fauna important for fish food. Various fishes from the seine net have been examined and shown to feed on the dominant invertebrates. A very interesting feature in these investigations is the work by Dr. Nicholls on sand-dwelling copepods, especially minute species living in the interstices between the sand grains on the beach. Several new species of these and three new genera have been found. Other researches include algal ecology and preserving colour in green seaweeds, experiments on timber preservation in the sea and the growth of the dog-fish *Acanthias*.

Seismology in New Zealand

THE report of Dr. C. E. Adams, Dominion Astronomer and Seismologist, for the year 1934 (*Dept. Sci. Indus. Res. Bull.*, No. 105) shows that the seismic activity of New Zealand was much greater during that year than in 1933, the number of earthquakes felt being 230, instead of 108. Of these, 158 were felt in the North Island only, 60 in the South Island only, and 12 in both islands. The most important shock was that of March 5 at 11.16 p.m. N.Z. time (11.46 a.m., G.M.T.). Its intensity in several parts of northern Wairarapa reached the degree 9 of the Rossi-Forel scale and chimneys fell over a wide area in the southern part of the North Island. The map that accompanies the paper shows that most of the epicentres lay in the extreme north of South Island and the southern half of North Island. Owing to the increased activity off the east coast of the latter island and to other changes that have been reported along the coast, it is strongly recommended that a detailed marine survey should be carried out of the whole east coast, including soundings in the seas to the east of New Zealand.

Solar Activity and Terrestrial Phenomena

IN 1924 the International Research Council (now transformed into the International Council of Scientific Unions) formed a Commission for the Study of Solar and Terrestrial Relationships, a field of science which extends over the domains of at least three of the International Scientific Unions. This Commission, among other activities, has published triennial reports, reviewing the state and progress of knowledge on solar and terrestrial relationships, and, where necessary, making recommendations regarding action that may conduce to further progress. These reports are distributed to certain libraries and to institutions and individuals occupied in work relating to the subject. The fourth report has recently been issued (Conseil International des Unions Scientifiques : Quatrième Rapport de la Commission pour l'Etude des Relations entre les Phénomènes Solaires et Terrestres ; pp. 159. Firenze, 1936) under the editorship of the president of the Commission, Prof. G. Abetti, Astrophysical Observatory, Arcetri, Italy. It differs from its predecessors in being better and more attractively produced, and in having a valuable 28-page introduction by the editor, giving a general survey of the subject for the past three years. The remainder of the volume consists of twenty-one brief articles on different aspects of the subject, by various authors.

Electric Supply in the Irish Free State

THE annual report of the Electricity Supply Board of the Irish Free State for the year ending March 31, 1936 shows that a further increase in the sale of electricity has been effected, and results in a surplus of income over expenditure of about £310,000. The total capital expenditure is now about 10½ million pounds, of which 5 per cent is paid to the State. The total sale of electric units during the year amounted to 187 millions, and the average receipts per unit dropped from 1·92*d*. to 1·84*d*. The figures show a very satisfactory acceleration in the development of the consumption of electricity for domestic purposes. In the environs of Dublin the consumption increased by 63 per cent. The total units generated during the year were 243 millions, of which 211 millions were supplied by the hydro-electric power station on the Shannon. Details are given of the extension of plant, and the building of new works on the Shannon and at the Pigeon House in Dublin. Two Swiss experts have reported on the development of the River Liffey for hydro-electric purposes. As it is the intention of the Corporation of the City of Dublin to use the water-storage reservoir on the Liffey to augment the ordinary water supply to the city, it was found inadvisable to take full advantage of the Liffey water-power project for six or seven years. As soon as the necessary legislative provision has been obtained, the work on the reservoir will be begun. The average yearly production of the Liffey hydro-electric development is computed to be 30 million units.

Scientific and Technical Literature

SEVERAL suggestions for the improvement of scientific and technical literature are made by Commander T. W. Macalpine in the *Publishers' Circular and the Publisher and Bookseller* of July 18. Criticizing the present procedure followed by a specialist or a publishing company in regard to a projected scientific book, he suggests that the exposition of the subjects treated in scientific and technical works, etc., would be improved, their utility for easy and quick reference increased, the cost of production decreased, and their filing and storage on shelves, etc., facilitated, if there existed an independent body of recognized standing in the world of science which could furnish authors and publishers with general information and guidance: At present an author is rarely able to give much information of assistance to the publishers on such matters as form of treatment, size of volume, number of words, type or types, number and kind of illustrations, diagrams, paper, binding. Accordingly, the utility of a book is liable to be limited by the publisher's experience. An independent advisory body of recognized standing which could supply information on such matters, assist in the standardization of nomenclature and symbolism, as well as of formats and sizes of printed area on pages, and advice on subdivision, synopsis, contents list and index, etc., would make an important contribution to efficient publication.

Composition of Cereal Straw

THE seemingly facetious title, "The Two Ends of Straw", appears over an article by Dr. H. Nicol in *Agricultural History* (10, No. 1, Jan. 1936), reviewing some early, but fundamental, research upon the composition of cereal straw. The work of Prof. J. F. W. Johnston in 1842, of J. P. Norton and P. F. H. Fromberg in 1845, and of J. I. Pierre in 1863 and 1866 is collected to show that straw has a great diversity of composition between the root end, and the parts towards the flower. The work of Pierre is particularly detailed, and supplies a great deal of material not widely known at the present day. Dr. Nicol discusses some of the results in relation to the recent hypothesis of 'negative migration' of plant constituents, where nitrogen and mineral elements are returned to the soil. Several additional papers upon the partitional analysis of straw have come to light since the publication of the article under review, but the most recent is dated 1879. There is considerable gratification, but also cause for humble reflection, that modern ideas are being confirmed by work which has remained in oblivion for nearly sixty years.

Greenkeeping Research

THE spring number of the *Journal of the Board of Greenkeeping Research* (4, No. 14, from the Board's Research Station, St. Ives, Bingley, Yorks, 2*s*. 6*d*. net) contains the annual report of the organization, which shows, *inter alia*, a very gratifying volume of advisory work. Many suggestions for future work of a practical kind have been made by the Greenkeepers' Advisory Committee, and the report of last year's annual conference is embellished by the full text of Prof. N. M. Comber's address on "The Constitution of Soil". Mr. R. B. Dawson, director of the Research Station, contributes a short but highly informative article on camomile lawns, and the previous accounts of lawn grasses, of weeds, and of fertilizers, are continued. The difficulties of accurate botanical description are being met by the publication of a glossary of botanical terms. Mr. R. B. Ferro discusses some of the difficulties of field experimentation on the golf course. Two short articles on water installations, a description of the management of a golf course on heavy clay soil, and a plea for special investigation of bowling green problems, are included in the issue.

A Journal of Marriage Hygiene and Birth Control

WITH the May issue (2, No. 4), *Marriage Hygiene* completes its second year. The objects of this quarterly journal are to secure for conjugal hygiene a proper place in preventive medicine, to publish scientific contributions treating marriage as a social and biological institution, and to promote and coordinate contraceptive clinics and marriage consultation centres in various parts of the globe. Each number contains notes and comments, original articles, reviews and abstracts of current literature. "The Positive Side of Birth Control" (E. B. Reuter), "Birth Prevention in France" (J. J. Spengler), and "Artificial Insemination" (H. Brewer) are some of the original articles in the present number. The yearly subscription for the volume of about five hundred pages is 18*s*. It is published from Kodak House, Bombay 1, India, the editor being A. P. Pillay. The London agents are Messrs. H. K. Lewis and Co., 136 Gower Street, W.C.1.

Anti-Noise Regulations

THE City Council of Philadelphia has adopted a noise abatement ordinance prepared by a Special Committee of the Philadelphia County Medical Society. The ordinance prohibits sounding of motor-horns except when absolutely necessary for the prevention of accidents, building operations at night except by special permit, the use of sound devices by pedlars, unnecessary noise in handling rubbish cans, and the use of gongs, sirens or exhaust whistles on any vehicles except those of the police and fire bureaux, and hospitals. Loud playing of radios in homes or in front of stores is also among the specific noises forbidden in the ordinance.

Costing Returns of Hospitals and Sanatoria

IN recent years, the value of costing methods in securing business efficiency has become increasingly recognized, not only in industry but also in local government. The Ministry of Health has issued Part 1 and Part 2 of the costing returns of hospitals for the year ending March 31, 1935 (H.M. Stationery Office, 1936. Price 1*s*. and 1*s*. 3*d*. net). Part 1 contains particulars of Poor Law hospitals, general hospitals administered by local authorities under the Public Health Acts or the Local Government Acts, sanatoria and other institutions for the residential treatment of tuberculosis, and maternity homes and hospitals. Part 2 contains the similar particulars for Poor Law institutions and separate casual wards.

Research at the London Hospital

THE annual volume of "Researches Published from the Wards and Laboratories of the London Hospital during 1935" has recently been issued (London: H. K. Lewis and Co., Ltd., 136 Gower Street, W.C.1. Price 7*s*. 6*d*. net). The matter has been selected and issued by the Publications Committee for Researches from the London Hospital, of which Prof. Bedson is honorary secretary. The volume includes twenty-seven papers, all published in various current journals, which cover a wide range of subjects included in the science and art of medicine.

A Large Sunspot

THE rising solar activity continues to yield, amongst other phenomena, a fairly high frequency of sunspots —about six groups a day being visible. These groups are usually of moderate extent, but about a dozen seen since the beginning of 1936 may be discriminated as naked-eye spots. These spots or groups of spots have areas of not less than 500 millionths of the sun's hemisphere or about 585 million square miles. The latest of these large spots is now crossing the sun's disk, from August 25 until September 6, with central meridian passage on August 30·7 U.T. Its growth to a large spot with multiple umbræ was considerable between August 27, when its area measured 400 millionths, and August 29, when it had increased to 900 millionths. The spot was surrounded by extensive faculæ, as seen in integrated light, and by flocculi as seen in hydrogen light ($H\alpha$) or in that of ionized calcium (H and K). There was marked activity recorded with the spectrohelioscope at the Royal Observatory, Greenwich, on August 27 and 28—in particular a bright eruption, visible in $H\beta$ as well as in $H\alpha$, on August 28 between 10^h and $11\frac{1}{2}^h$.

Announcements

FOLLOWING her record-breaking westbound passage across the Atlantic from Bishop Rock to the Ambrose Lightship, the *Queen Mary* has recently beaten the eastbound record. She passed Bishop Rock at 7.12 hr. G.M.T. on August 30, having taken 3 days 23 hr. 57 min. for the crossing. The average speed for the voyage of 2,939 miles was 30·63 knots, as compared with the average of 30·31 knots for the 3,015 miles which gave the *Normandie* the blue riband of the North Atlantic in June, 1935.

A WORLD Peace Conference is being held at Brussels on September 3–6. It has been organized by the International Peace Campaign; the Viscount Cecil and Pierre Cot are joint presidents; Miss Rose Manus, 48 Boulevard Botanique, Brussels, is the international secretary; Dame Adelaide Livingstone is vice-chairman of the British National Committee, which has its office at 27 Chester Terrace, Eaton Square, S.W.1. The Congress has special committees on medicine, science and education, and will raise general points, too, likely to be of interest to scientific workers.

DR. FRIEDRICH KÜSTNER, of Mehlem a. Rh., professor of astronomy and formerly director of the observatory of Bonn University, celebrated his eightieth birthday on August 28.

AN Institute for Industrial Medicine has recently been inaugurated in Milan.

THE twenty-fifth Congress of the German Society of Legal and Social Medicine will be held at Dresden on September 17–19. Further information can be obtained from Dr. Schrader, Lahnstrasse 9, Marburg a.d. Lahn.

THE Association for Photographic and Cinematographic Documentation in Science will hold a Congress in Paris on October 9–15. Further information can be obtained from Dr. Claoué, rue Scheffer 39, Paris, 16e.

ERRATUM.—In the letter entitled "Measurements of Cosmic Rays in a Deep Mine" by Drs. J. Barnóthy and M. Forró in NATURE of August 22, p. 325, lines 9 and 15, for "2,500 m." read "1,500 m."; line 15, for "0·09" read "0·18".

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A lecturer in electrical engineering in the Borough Polytechnic, London, S.E.1—The Principal (September 9).

A lecturer in mechanical engineering in the Handsworth Technical College, Golds Hill Road, Handsworth, Birmingham—The Principal (September 12).

A junior bacteriologist in the University of Bristol —The Registrar (September 12).

A vice-principal (industrial and/or mining engineering) of the Wakefield Technical College—The Director of Education, Education Department, 27 King Street, Wakefield (September 14).

An assistant lecturer in mathematics in the University of Sheffield—The Registrar (September 15).

An investigator for research in problems of falls of ground and haulage in coal mines to the Safety in Mines Research Board—The Under Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, London, S.W.1 (September 19).

A demonstrator in mechanical engineering in the University of Leeds—The Registrar (September 21).

A regius professor of natural history in the University of Aberdeen—The Private Secretary, Scottish Office, Whitehall, London, S.W.1 (October 31).

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 407.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Radio-Helium

THE following experiment concerning the nature of the radioactive element produced in beryllium when bombarded by fast neutrons[1] was made on the suggestion of Dr. O. R. Frisch.

Beryllium was precipitated as a hydroxide in a very fine-grained form (this was kindly done for us by Prof. G. v. Hevesy), so that it might be able to give off any helium produced in the process. The $Be(OH)_2$ powder was bombarded by neutrons from a beryllium-radon source of about 200 mc. strength, and a stream of hydrogen was at the same time passed through the tube containing the $Be(OH)_2$ and then through a capillary tube to a thin-walled jacket around a thin-walled Geiger counter. The distance between the neutron source and the counter was 60 cm., and the latter was properly shielded by lead.

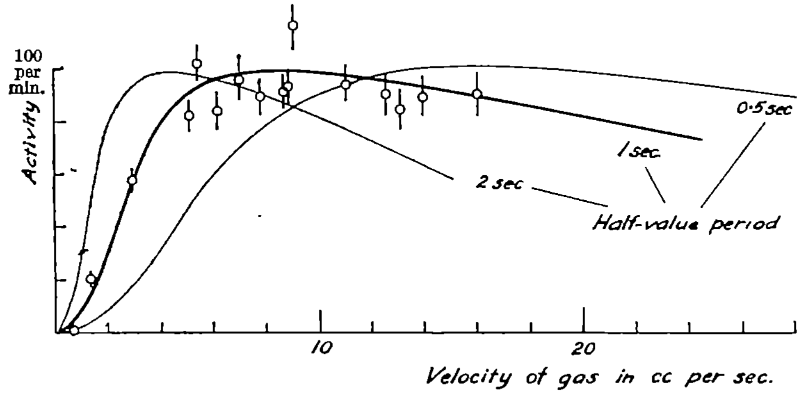

FIG. 1.

When the velocity of the gas was zero, the rate of counting was 20 per minute: when the velocity of the gas was increased, the counting rate increased as shown in Fig. 1, where the counting rate (less the γ-ray effect of 20 per min.) is plotted against the velocity of the hydrogen. This shows that a radioactive body in a gaseous state is produced in the $Be(OH)_2$. From the volumes of the $Be(OH)_2$ tube, the capillary and the jacket around the counter, one can calculate roughly the shape of the curve for the cases of the activity having a half-value period of 0·5 sec., 1 sec. or 2 sec. These curves are drawn in Fig. 1, and it is seen that the activity has a half-value period of about 1 sec., thus being identified as the one previously reported[1].

A radioactive gas produced by bombarding $^{9}_{4}Be$ by neutrons could scarcely be anything but $^{6}_{2}He$ or possibly $^{8}_{2}He$.

β-Ray Spectrum of Radio-Helium

IN order to investigate the energy distribution of the β-rays from radio-helium[1], we have employed an expansion chamber constructed by Dr. J. C. Jacobsen and kindly lent to us. In the middle of the top plate, a thin-walled brass cylinder (0·05 gm. per cm.², 1·5 cm. diameter) was inserted, into which an activated beryllium cylinder could be dipped. The latter was made of beryllium powder (0·12 gm. per cm.²) stuck on to a brass tube (0·1 gm. per cm.²) and could be moved automatically from a position around a neutron source (beryllium-radon) to the position in the Wilson chamber in 0·4 sec., this movement also starting the timing arrangement for expansion and light. A suitable lead shielding was arranged which cut down the electrons due to the γ-rays to a number small compared with the number of β-rays. The radioactivity induced in the brass tube carrying the beryllium is negligible as the latter is exposed to the neutrons only for a few seconds at most every minute.

The β-rays were bent by a magnetic field of 1,500 oersteds. The gas in the chamber was air at about half an atmosphere pressure, the condensing vapour a mixture of ether and alcohol.

Radio-helium emits negative electrons. 120 tracks have been measured and corrected for the stopping power of the brass cylinder and half of the beryllium layer. The uncertainty in the individual values of $H\rho$ is estimated to be about 10 per cent. The energy spectrum obtained is shown in Fig. 1. As usual, it is somewhat difficult to determine the upper limit: the scarcity of tracks in this region tends to give a value which is too low, whereas the

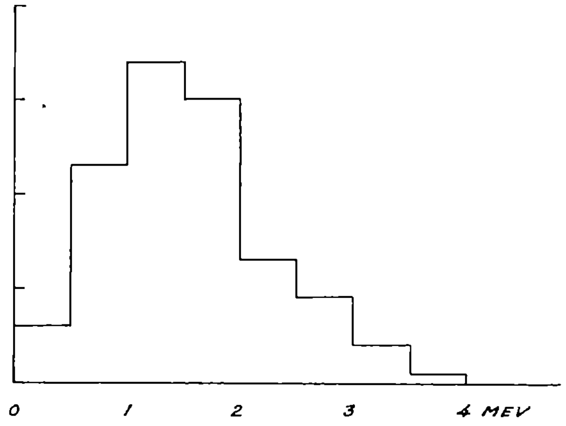

FIG. 1. Energy spectrum of β-rays from radio-helium.

uncertainty of the individual tracks tends to give a value which is too high. We consider 3·7 ± 0·5 m.e.v. as the most probable value from our measurements.

The most reasonable assumption as to the formation and disintegration of radio-helium are the processes :

$$ {}^9_4\mathrm{Be} + {}^1_0n \rightarrow {}^6_2\mathrm{He} + {}^4_2\mathrm{He} \qquad (1) $$

$$ \text{and } {}^6_2\mathrm{He} \rightarrow {}^6_3\mathrm{Li} + e^- \qquad (2) $$

If the energy release in (2) is 3·7 m.e.v., the mass of ${}^6_2$He would be 6·0207, using the masses given by Oliphant[2]. Recently Oliphant has reported[3] that (1) takes place even if the bombarding neutrons have only 1·5 m.e.v. kinetic energy. If these figures are applied in (1), it follows that the energy available for the breaking up of the intermediate ${}^{10}_4$Be nucleus into He and ${}^6_2$He is 0·8 m.e.v., which does not seem unreasonable.

We wish to thank Prof. N. Bohr for his interest in the work, and the Radium Institute of Copenhagen for the gift of the emanation.

Passage of Fast Electrons through Matter

WHEN a fast electron passes through matter, it loses its energy mainly by emission of a few large quanta of radiation (*Bremsstrahlung*). The radiation quanta are absorbed again, the absorption being due mainly to the creation of pairs. Thus, in a *thick sheet of matter*, a fast primary electron produces quite a number of secondary positive and negative electrons, which appear as a *small shower* giving rise to triple coincidences, etc.

Using the cross-sections for the above processes as obtained from relativistic quantum mechanics[1], we have calculated the probability for the production of secondary electrons with an energy greater than E, say, when a primary electron of energy E_0 passes through a sheet of matter of thickness L. The result can be expressed in the same form for all materials if the thickness L is expressed in certain units characteristic for the material. The unit thickness ($L = 1$) corresponds to :

0·40 cm. Pb; 7·4 cm. Al; 33 cm. H_2O; 280 m. air.

The average number of positive *or* negative electrons emerging from the sheet depends only on L and the ratio E_0/E. It is given in the accompanying table (the total number of positive + negative electrons being twice the corresponding figure given in the table) :

E_0/E	20	100	400	1000	10,000
$L = 2$	0·5	1·3	2	2·5	3·7
3	0·7	1·8	3·4	4·4	7
4	0·7	2	3·8	5·2	8·6
5	0·5	1·8	3·8	5·4	9·3
7	0·2	1·2	3	4·7	10·3
10	0	0·5	1·8	3	8·4

The results are only valid for $E \gg mc^2$.

The table shows that the maximum number of secondaries is produced at a thickness L_m of about 3·5 – 5, increasing slowly with E_0/E. $L = 4$ corresponds to 1·6 cm. lead. For this thickness a primary electron of 2×10^9 e.v. produces, for example, on the average 2 positive and 2 negative electrons with energies greater than 20×10^6 e.v.

There can be no doubt that the process discussed above is responsible at least for a large part of the triple-coincidences obtained by Rossi and others. The thickness $L_m = 4$ (1·6 cm. lead) at which the number of secondaries is a maximum agrees well with the maximum of Rossi's well-known curves[2].

Showers of this sort can also be produced by hard light quanta. After having travelled an average distance $L = 1·7$, the light quantum creates a pair, each electron of which produces secondaries in the way described above.

A more detailed discussion of these processes and in particular of the higher stages (tertiary, quaternary . . . electrons) will be given elsewhere. The latter have to be taken into account for large values of L and E_0/E.

Intrinsic Uncertainty of Reference Frames

PHYSICAL ideas which seem at first sight somewhat arbitrary become, as Eddington has stressed, almost inevitable when the relativity principle is taken to its proper conclusion. As examples may be quoted the law of gravitation, in which the radius of curvature anywhere in the universe is proportional to the corresponding amount of matter there, and the principle of unit weights (equal *a priori* probabilities) in statistical mechanics.

Eddington has pointed out further, following earlier ideas of Mach, that the *ad hoc* introduction in quantum theory of a term m to represent mass is theoretically unsatisfactory, in view of the necessary dependence of such a term on the remaining unspecified matter. It seems logical to realize not only that relativity has denied the absolute independence of mass, space and time ; but also that these concepts should rigorously be regarded merely as aspects of the configuration and changes of configuration of matter. On any kind of atomic theory it follows that these three associated concepts of mass, space and time are all statistical in character.

Any mechanical properties of a system will be implicitly affected by fluctuations in our frame of reference. If in particular we use the rest of the world as our reference frame, there will be an uncertainty of order $R/\sqrt{N}$, where R is the radius of the universe, and N the number of particles it contains. From this uncertainty, Eddington has considered what term should represent the 'reference mass' of the universe. If this statistical view of the origin of mass is accepted, it does not seem unreasonable that we should assume a corresponding uncertainty of the conjugate co-ordinate, proper time, of order h/mc^2 or $R/c\sqrt{N}$.

The above argument could thus be regarded as one approach to Flint's assumption that in addition to the usual limitations imposed by Heisenberg's uncertainty principle, there is a limit to the subdivision of proper time, from which postulate he shows that a paradox of negative energy levels disappears[1]. It seems in any case significant that the order of these uncertainties is that at which it is known that wave mechanics begins to break down.

A further conceivable development of the argument is its connexion with changes associated with a direction of time. If recognizable changes of configuration could be imagined referred to an ideal time defined in terms of the number of interactions that take place, then as entropy increases, the approach of equilibrium will imply that more interactions will take place before a recognizable change occurs. If our observable time is regarded as dependent on recognizable change, then, being a statistical average, it will as a macroscopic phenomenon eventually disappear. Before this stage is reached, however, it will in terms of our ideal time go more and more slowly; and it could appear to follow, if we adopt conventionally a fixed relation between measurements in space and time (denoted by the constant c), that space will correspondingly expand. Equivalently, the velocity of light could be said to decrease, though it should be noted, in view of past suggestions (on rather insufficient evidence), that this velocity *is* apparently decreasing, that even the present observed expansion of space, whatever its cause, would, on the assumption of an absolute constant for the velocity, only give rise to an apparent decrease of about 16 cm./sec./year, which would be undetectable[2].

In spite of possible fallacies in the above arguments, they may serve to stress properties of an observable time that are now perhaps becoming appreciated. Thus it should be remembered that a clock is not merely an oscillating system that is observed at a particular instant—this would define in terms of space a periodic sort of time; if it has also to record its *number* of oscillations without disturbance, it begins to be a more complicated mechanism.

Genotypic Control of Chromosome Size

The differences in size between the chromosomes of related species are usually differences that can be attributed to structural changes such as fusion, fragmentation, etc. In many groups, however, enormous differences of size are found, which may be of the order of 1 : 100 or even 1 : 1,000. Such differences, uniformly affecting as they often do the whole complement, must be due to a unitary genotypic control of chromosome size. In other words, the size of chromosomes, like other properties of the organism, must be subordinate to the action of the genes they carry[1].

Experimental examples of this principle are very rare, the only clear case being that of a bud sport in a triploid plant presumed to be a hybrid between diploid and tetraploid *Tradescantia* species with different chromosome sizes. The mutant had chromosomes 1/5 the size of the stock[2].

In experimental material of grasses[3], kindly supplied by Dr. T. J. Jenkin, of the Welsh Plant Breeding Station, Aberystwyth, I have been able to find evidence of the inheritance of this genotypic property governing chromosome size. A male sterile plant of *Lolium perenne* (Fig. 1, *A*), with chromosomes of about a quarter the size of the normal, was crossed with a normal plant and gave 8 male sterile seedlings, two of which were examined. One of them (Fig. 1, *B*) proved to have chromosomes of normal size for the species. The other (Fig. 1, *C*) has chromosomes of more than twice this size.

I have found similar differences in crosses between *Festuca arundinacea* and *F. pratensis*[4].

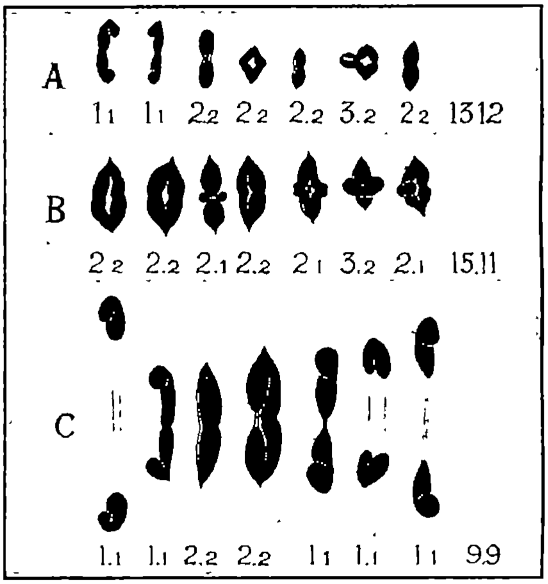

Fig. 1. Metaphase and early anaphase bivalents in three *Lolium perenne* plants. *A* is the female parent of both *B* and *C*. Total and terminal chiasmata are given under each bivalent. Aceto-carmine preparations. × about 1,700.

Further study will be necessary to determine the mode of inheritance of this character, but the present observations prove that it is subject to Mendelian segregation. They therefore throw doubt on statements that characteristic chromosome size differences between species are maintained in their hybrids. Some of these statements have already been disproved[5].

Behaviour of Local *Drosophila melanogaster* during Late Larval Stage

During March 1935 a few local *Drosophila* flies which emerged from the soil and leaves of a millipede culture of Dr. N. F. Paterson were collected, and a culture was started. The stock proved to be of good viability; the flies were identified as *Drosophila melanogaster*. After the cultures had been kept for a few generations it was observed that the larvæ of this 'Witwatersrand' stock displayed an interesting difference in behaviour compared with the standard *D. melanogaster* cultures. During their late larval stage, the larvæ of the latter, in order to pupate, creep up against the side of the culture bottle, whereas those of the 'Witwatersrand' stock only very occasionally behave in this manner, the great majority pupating on or even in the culture medium. We tentatively labelled this behaviour as 'positive hydrotropism' in contrast to the general 'negative hydrotropism' of *D. melanogaster*.

This positive behaviour apparently is the cause of the high percentage of wing abnormalities observed in our 'Witwatersrand' cultures, for when the flies emerge from the moist culture medium their wings often fail to unfold normally.

On April 14 this year, a random culture of our Witwatersrand stock was used for two series of selection experiments, a negative and a positive series. This culture had eight pupæ on the side of the bottle and between 150 and 200 on the culture medium. The negative series started with the eight pupæ removed from the side of the bottle, and the positive series with the pupæ on and in the culture medium. This method of selection was effected for each generation obtained. It follows that the number of parents each time for the negative series was very small in comparison with that of the positive series. This notwithstanding, the eight generations so far obtained for the negative series show an average of 38 negative pupæ per generation, and an average of only 10 negative pupæ for the six generations so far obtained for the positive series. The negative pupæ in the latter, after being counted, were always destroyed, and only the positive pupæ used; in the former only the negative pupæ were used.

It seems justified to conclude that this negative behaviour differs innately from the general positive behaviour of our Witwatersrand stock. Probably multiple factors are involved. This general positive behaviour again differs innately from the general negative behaviour of the standard stocks of *Drosophila melanogaster*.

Furthermore, several experiments have been made to cross our Witwatersrand stock with the standard *D. melanogaster* stocks, but without success.

It seems reasonable to conclude that our local Witwatersrand stock must belong to a geographic race of *D. melanogaster*.

We are indebted to Dr. Smart of the British Museum and to Dr. Paterson of the University of the Witwatersrand for the trouble taken to identify the flies, and also to Messrs. Paff and Bosazza for the photographs taken.

Creeping Movements of *Spirogyra*

THERE are several references in the literature to the movement and behaviour of masses of the alga *Spirogyra* when kept under water in a vessel. Hofmeister[1] described the unravelling of the filaments into wave-like hanks; this he believed to be due to the action of light. The same author, Oltmanns[2] and Langer[3] have also described the way in which the algal threads creep considerable distances up the sides of a containing vessel. Oltmanns suggested that the latter movement might be related to a secretion of mucilage from the cells. Langer showed that it was not a growth movement, and that it took place more rapidly and vigorously in the dark than in the light.

We have carried out a series of experiments to discover the effect of non-plasmolyzing solutions of various electrolytes and non-electrolytes upon the extent of these creeping movements in a species of *Spirogyra* tentatively named as *S. longata* Vauch. The method employed was the same for all experiments. A fixed quantity by weight of the alga was placed in a series of different solutions of electrolytes and non-electrolytes in tap water, of concentrations ranging from 0·0 per cent to 1·0 per cent contained in similar test-tubes. The volume of the solution was constant for all the experiments. Since it was found that light had an inhibiting effect upon the creeping movements, the experiments were carried out in the dark. Measurements of the heights climbed above the meniscus of the solution were made after a period of twenty-four hours.

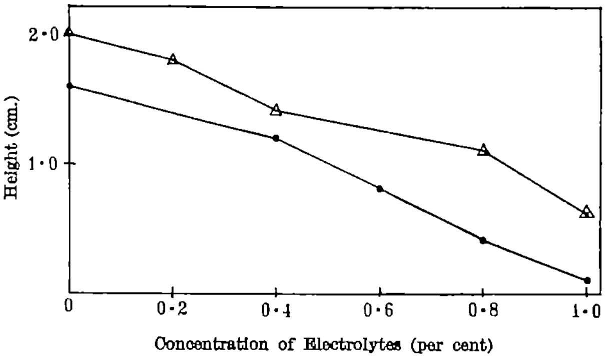

FIG. 1. Graph to show the relation between the extent of climbing and the concentration of electrolytes; —△—△—, potassium nitrate; —●—●—, sodium chloride.

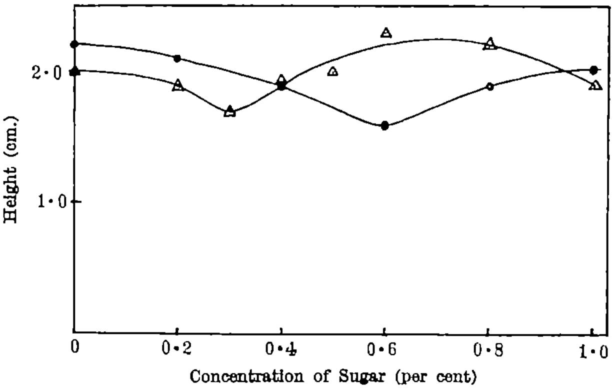

FIG. 2. Graph to show the relation between the extent of climbing and the concentration of non-electrolytes; —△—△—, sucrose; —●—●—, dextrose.

Using electrolytes such as sodium chloride and potassium nitrate, it was found that with increasing concentration of the electrolyte there was a corresponding decrease in the climbing effect. This is illustrated by Fig. 1.

Using non-electrolytes such as dextrose and sucrose, it was found that up to a certain definite concentration the behaviour was very similar to that obtained using electrolytes. Beyond this point, however, the effect was reversed and a further increase in concentration caused an increase in the extent of climbing (Fig. 2).

There seems to be a parallel between our observations on the effect of sugars upon the extent of climbing of these algal filaments and those of Maige and Nicolas[4] upon the effect of sugar solutions on the respiratory activity of various plant tissues. The latter showed that, during the first period of immersion in a sugar solution, a plant tissue showed a period of decreasing respiratory activity followed by one of increasing activity during the period of sugar penetration.

It is hoped to carry out further experiments to determine the effect of electrolytic and non-electrolytic solutions upon the rate of respiration of this alga, and also to develop a more accurate quantitative method of measuring the extent of the climbing phenomenon.

The Electric Quadrupole Moment of the Nucleus ${}^{127}_{53}$I

THE hyperfine structures of many terms in the arc, as well as in the first spark, spectrum of iodine show deviations from Landé's rule[1]. As Murakawa has pointed out, the cause of this may be an electric quadrupole moment of the nucleus. The existence of such nuclear quadrupole moments was shown for the first time by Prof. H. Schüler and me in europium and cassiopeium[2]. The exact theory was given by H. Casimir[3]. In the case of iodine the frequent occurrence of deviations leaves no doubt that they are due to the same cause. Because the electronic structure of the terms is very complicated, most of them are not suited for a determination of the quadrupole moment. The best term is $5p^4\,6s\;{}^4P_{5/2}$ of I I measured by Tolansky. Its eigenfunction is approximately the product of the $6s$ eigenfunction and the eigenfunction of the $5p^4\;{}^3P_2$ term of I II. The latter can be determined from the coarse structure, using the theory of intermediate coupling. By calculations analogous to those for bismuth[4] one gets from Casimir's formula and Tolansky's measurements a value of about $-\,0{\cdot}2 \times 10^{-24}$ for the nuclear electric quadrupole moment of iodine. That the sign is negative, one may infer also from the term $5p^3\,({}^2D)\,6s\;{}^3D_2$ measured by Murakawa.

Two remarks should be added: first, Murakawa and Tolansky have determined the spin of iodine only by means of the interval rule. As we know it fails in most terms, the value of 7/2 cannot be excluded at present. Secondly, the structure of ${}^4P_{5/2}$ of I I was deduced by Tolansky under the assumption that the combining higher levels have no perturbation. His measurements on several lines seem to show that ${}^4P_{3/2}$ and most of the higher levels have deviations in the same direction as ${}^4P_{5/2}$. This would make the deviation in ${}^4P_{5/2}$ somewhat greater.

All one can say at present is, that the sign of the quadrupole moment is negative and that its value is smaller than $-\,0{\cdot}5 \times 10^{-24}$. The negative sign indicates that the charge distribution is flattened in the direction of the spin axis. It may be noted that the positive quadrupole moments now determined (^{75}As, ${}^{151,\,153}$Eu, ^{175}Cp, ^{201}Hg) have values ranging up to 5×10^{-24}, whereas the negative quadrupole moments (${}^{63,\,65}$Cu, ^{127}I, ^{209}Bi) all have values[5] smaller than $-\,0{\cdot}5 \times 10^{-24}$.

Note added in proof: Recently, L. A. Strait and F. A. Jenkins[6] have shown by means of intensity measurements in the band spectrum that the spin of iodine is 5/2.

[6] L. A. Strait and F. A. Jenkins, *Phys. Rev.*, **49**, 635 (1936).

IN the preceding note, which the Editor of NATURE has been good enough to let me see in advance of publication, Schmidt, following Murakawa[1], suggests that the frequent occurrence of perturbations in terms of both the arc and spark spectra of iodine indicate a nuclear quadrupole moment. This may be correct, but as I have shown that at least in the spark spectrum[2] term interaction perturbation occurs, and in view of the complex electronic structures involved, it is very likely that the perturbations may be due to either of the above causes or possibly both, depending upon individual terms (that is, if a quadrupole moment is assumed to exist). This fact makes caution desirable and any calculation of the quadrupole moment can only be very approximate. Schmidt has been obliged to employ my measurements for the arc spectrum, and as I have previously pointed out, the structures in this spectrum are not so well resolved as in the spark spectrum. His calculation is therefore based upon a small deviation from the interval rule in which I was not able to prove whether more than one level was affected, so that the type of perturbation is uncertain.

Regarding Schmidt's suggestion that the spin may be 7/2, it may be pointed out that Murakawa[3] (spark spectrum), Tolansky[4] (arc spectrum, spark spectrum) and Lacroute[5] (Zeeman effect) all give 5/2. This value may be considered as certain, therefore, particularly in view of the Zeeman effect support.

The approximate quadrupole moment suggested by Schmidt is of course only tentative. I am engaged now in investigating the fine structures in the ultraviolet lines of the iodine spectra with the view of obtaining further data.

Monomolecular Layers of Chlorophyll

IN order to study the properties of monomolecular layers of chlorophyll, a mixture of the modifications *a* and *b* in the proportion 3 : 1 (the proportion encountered in living plants), furnished by Prof. Stoll of Basle, was dissolved in ether or acetone. The solution was first added to pure water, to 0·01 normal and to 0·1 normal sulphuric acid. The relation obtained between area and pressure showed that a monomolecular layer actually is formed. No noticeable difference was found between the case of pure water and that of the acid, so that all the results can be incorporated in Curve I (Fig. 1). The spreading with a solution in acetone is recommended because on account of the greater volatility of the ether, traces of solid chlorophyll frequently remain at the opening of the pipette, making it more difficult to obtain reproducible values. Curve I corresponds to a film of the liquid type. The limiting area per molecule at zero compression is 124 A.^{2}, a value in satisfactory agreement with the value of about 133 A.^{2}, recently given by Hughes[1]. The small difference probably is due to impurities. At a pressure of about 26 dynes per cm. the film becomes polymolecular, the curve becoming a horizontal line.

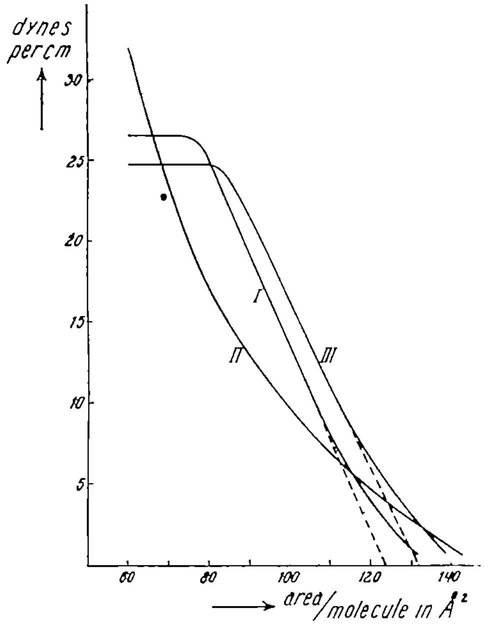

FIG. 1.

As the chlorophyll molecule possesses several double bonds, another curve was expected when spreading on an acid solution of potassium permanganate. This expectation proved to be justified. Curve II was obtained on a 1 per cent solution of potassium permanganate in 0·1 normal sulphuric acid. Over the whole range, but more particularly at small pressures, the film is more compressible than the films previously studied. It was impossible for us to measure the pressure where the film becomes polymolecular, this pressure being too high for registration by the instrument used.

Finally, the behaviour of chlorophyll on water containing carbon dioxide was studied. Great care had to be taken not to have the water oversaturated with carbon dioxide. Ultimately the experiments were carried out on water in equilibrium with carbon dioxide at one atmosphere. The results are contained in Curve III. The molecule appears to require a greater space under the influence of carbon dioxide, having a limiting area of 132 A.^{2}. That this is not due to the acid character of the solution is indicated by the experiments on sulphuric acid. The pressure required to make the film polymolecular is slightly less than in the case of pure water. Experiments with nitric oxide showed that this gas, which in its physical properties (solubility, etc.) strongly resembles carbon dioxide, has no effect.

In conclusion, I wish to express my thanks to Prof. E. Gorter in Leyden for the loan of a Langmuir trough of special construction, which enabled me to work in atmospheres other than air. Also I am much obliged to Prof. Prins for putting at my disposal the sample of chlorophyll and for suggesting the investigation on water containing carbon dioxide, to Dr. J. H. P. Jonxis for valuable advice concerning the technique of the experiments, to Dr. R. de L. Kronig for stimulating discussion and to Messrs. J. Vermeer and F. H. Robaard for their kind help in the performance of the measurements.

Contact Potentials of Reversible Soluble Films of Lauric Acid

WHEN a nearly saturated solution of lauric acid in distilled water is placed in an Adam-Jessop film-pressure trough, the soluble adsorbed film may be compressed or swept in the same manner as an insoluble film of a higher fatty acid. However, the surface is rapidly replenished by diffusion from below, after sweeping, or the compressed film diffuses downward. In either case the reading of the film-balance returns to zero, in a period of about thirty minutes at 25° C. Similar effects have been noticed with benzopurpurin solutions[1] and with soap solutions[2]. Since the contact potential of solutions is proportional to the concentration of the surface-active solute, simultaneous contact potential measurements with a polonium-covered silver electrode on the above surfaces might be expected to yield potential-time curves nearly parallel to the force-time curves. Such proved to be the case, with the following notable differences.

Referred to a pure water surface as zero, the contact potential of a nearly saturated surface of lauric acid solution is −120 mv. Upon sweeping rapidly, the surface tension of the swept surface rises about five dynes and returns to its original value slowly. The surface potential immediately after sweeping rises to 0 mv., and falls rapidly to − 100 mv. in twelve minutes, whilst the surface tension has changed but a dyne per centimetre. This result is to be expected, since the first film to be formed by diffusion from below is necessarily dilute, and contributes but a small surface pressure, but a large change in surface potential. After twelve minutes the film becomes more close-packed, and the surface tension falls more rapidly, while the potential changes but slightly, in complete accordance with the results of Harkins and Fischer[3] on lauric acid films spread by the aid of a solvent.

Upon compression, the pressure may rise to so high as 25 dynes per centimetre, while the potential drops to − 200 mv. Both surface potential and surface pressure return to their equilibrium values in half an hour, the surface pressure falling very rapidly, due to solution of the compressed film, to a value of 6 dynes per cm., in two minutes. This is again in accordance with expectations, since Harkins and Fischer found that a highly compressed film of lauric acid lowers the surface potential about 80 mv. more than that of a dilute film.

These results indicate that (1) the time element is very important in the determination of surface tension of solutions of surface-active materials, (2) determinations of surface potentials by dynamic methods (such as Kenrick's jet method) are unsuited for examination of solutions of materials such as these which require considerable time for equilibrium in the surface.

The work is being continued on solutions of undecylic acid.

The results obtained by Bouhet[4] by an optical method may be mentioned as further evidence that sweeping a solution of a higher fatty acid removes the adsorbed film, the swept surface then having the physical properties of a pure water surface.

Dissociation Pressure of Copper Sulphate Pentadeuterate

J. R. PARTINGTON and K. Stratton[1] have found by a tensimetric method the dissociation pressure of copper sulphate pentadeuterate to be 6·655 mm. Hg at 25° C., and 9·285 mm. Hg at 30° C. One of us, in collaboration with H. Perpérot[2], has constructed a tensimeter by means of which he ascertained in a preliminary experiment that the dissociation pressure of copper sulphate pentadeuterate is lower than that of the pentahydrate. Continuing this research, we have modified the original tensimeter so that the pressures are now measured by means of an ordinary shortened manometer instead of a differential one, the new results being as follows :

° C.	20	30	40	50	60
mm. Hg	4·4	9·9	21·0	42·1	80·9

For 25° the value of 6·5 mm. Hg is found by interpolation.

The pressures obtained are in good accord with those measured by Partington and Stratton, giving in addition a wider range of temperature. The value published in collaboration with H. Perpérot[2], which is mentioned by F. T. Miles, R. W. Shearman and Alan W. C. Menzies[3], was not intended to be exact, as is seen from the fact that it was rounded off to whole units and mentioned only in passing in a paper describing the apparatus, and is decidedly a little too low, whereas the measurements of Miles, Shearman and Menzies lead, on the contrary, to dissociation pressures a little too high, if we understand these authors rightly.

The aim of the communication published with H. Perpérot was not to give a precise value of the dissociation pressure of copper sulphate pentadeuterate, but to show only that this pressure is lower than that of the pentahydrate, which is corroborated by experiments of the authors quoted.

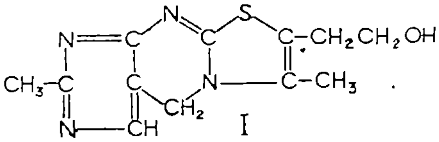
Synthesis of Thiochrome

THE formation of thiochrome by oxidation of aneurin (vitamin B_1) with alkaline potassium ferricyanide was first reported in these columns[1]. Continuation of our synthetic work[2] has resulted in the synthesis of thiochrome. 2-Methyl-4-chloro-5-chloromethylpyrimidine, synthesized from 2-methyl-4-hydroxypyrimidine-5-acetic ester, was condensed with 2-amino-4-methyl-5-β-hydroxyethylthiazole. The condensation product (I) proved to be identical with thiochrome prepared from aneurin ; the melting point of both substances was the same (225°–226°) and the melting point of the mixture showed no depression.



I

The intense blue fluorescence shown by thiochrome appears to be a property of the condensed ring system present in the molecule, for we have prepared other compounds of this type, all of which have a similar fluorescence. This synthesis affords independent proof of the structure of aneurin, the synthesis of which has just been reported by Williams and Cline[3].

Full details of the work will be published elsewhere.

The Amylase System of Rice Grain during Ripening and Germination

THE formation and properties of α- and β-amylases in germinating grains have been frequently studied by many investigators. Some workers[1] believe that dormant grains contain only β-amylase which increases during germination, while α-amylase appears only during sprouting. Others[2] consider that the increase in amylolytic activity during germination is not a fresh enzyme formation, but is due to an activation by an activator of organic nature, 'amylokinase', which arises during the process of germination, or to an increase in the soluble part of the amylase, especially in the case of the β-component, which increase is based on proteolytic decomposition. Our researches on the amylolytic changes during ripening and germination of rice grains have thrown fresh light on this important question. The results thus far obtained may be briefly summarized as follows.

The rice grain contains both α- and β-amylases, which are differentiated by their hydrolysis on amyloamylose, according to the method introduced by Samec and Waldschmidt-Leitz[3]. These two amylases are further differentiated by their differences in *p*H optima, the α- and β-amylases having their optima at *p*H 7·0 and 4·6 respectively. At their optimum *p*H, they behave like pure α- and β-amylases in their hydrolysis of amyloamylose. In the case of the amylase the optimum *p*H of which lies at *p*H 7·0, the iodine colour end-point (violet) was reached without any measurable maltose formation. This observation demonstrates for the first time the occurrence in plants of an amylase of *p*H optimum 7·0, which in the early stages of starch digestion yields no reducing groups.

These two enzymes are present in the dormant seed, and exist largely in the insoluble condition, so that they cannot be extracted with water, but they can be obtained in an active state by extraction with phosphate buffer (*M*/15) at *p*H 7·0. The α-amylase becomes inactive (in the sense that it cannot be extracted with water) as ripening advances, and again becomes active during germination. In the light of these findings, it can be said that the view put forward by Ohlsson and co-workers, that the amylase arises only during the germination of grains, is untenable. Further work on the behaviour and nature of these enzymes during germination and storing, their distribution in the seed and their relation to the cooking quality of rice is in progress.

Points from Foregoing Letters

WHEN beryllium is bombarded by fast neutrons, a radioactive substance is produced of half-period about one second. New experiments by Dr. T. Bjerge show that it is a gaseous substance, probably helium of atomic mass six or five. The energy distribution of the β-rays (electrons) emitted by this radioactive gas has been measured by Dr. T. Bjerge and Dr. K. J. Brostrom, and agrees with the view that the electrons arise during the transformation of helium atoms of mass six into lithium atoms of the same atomic mass.

The probability for the production of secondary electrons when a fast primary electron passes through various thicknesses of matter has been calculated by H. J. Bhabha and Dr. W. Heitler. A primary electron of 2×10^9 electron volts energy, passing through a thickness equivalent to 1·6 cm. of lead, produces, on the average, two positive and two negative electrons, with energies greater than 2×10^7 e.v.

M. S. Bartlett discusses further aspects of the uncertainty principle applied to time, and conceives that, in relation to an ideal time defined in terms of the number of interactions that take place, our observable time may slow down, as the universe approaches equilibrium. Such a 'slowing down' of observable time would be equivalent to an expanding universe or a decrease in the velocity of light.

The occurrence of chromosomes of double normal size in a male sterile specimen of the perennial rye-grass, *Lolium perenne*, is described by P. T. Thomas. The mode of inheritance indicates that chromosome size is subject to Mendelian segregation.

Drosophila cultures derived from flies collected on the Witwatersrand and bred by Dr. G. Eloff, although identified as *D. melanogaster*, nevertheless show a remarkable innate difference in behaviour in that during late larval stage, contrary to the general behaviour of the standard *D. melanogaster* cultures, the larvæ stay on or even in the culture medium in order to pupate; also, crosses between the two types of stocks are sterile.

Spirogyra, in the dark, climbs up the sides of the containing vessels. Solutions of electrolytes such as sodium chloride or potassium nitrate up to one per cent in concentrations—which do not produce collapse due to loss of water (plasmolysis)—are found by D. R. Chesterman and C. L. Foster to reduce the creeping. With non-electrolytes the behaviour up to a definite point is similar; beyond this point it is reversed. The authors suggest that these results may be related to effects upon the respiratory activity of the algal cells.

From measurements of the iodine hyperfine structure Dr. Th. Schmidt concludes that the iodine nucleus has a negative electric quadrupole moment smaller than $-0{\cdot}5 \times 10^{-24}$. The negative sign means that the charge distribution is flattened in the direction of the spin axis. Dr. S. Tolansky points out that the perturbations upon which Dr. Schmidt's calculations are based may have a different origin, and therefore the approximate quadrupole moment suggested can only be considered tentative.

From experiments with monomolecular surface films of chlorophyll, W. Sjoerdsma finds an area per molecule of 124 square Angstrom units. Under the influence of carbon dioxide, the chlorophyll molecules appear to require a greater space (132 $A.^2$).

The rate of change in surface pressure and in the contact electrical potential when the surface of a solution of lauric acid is swept clean of its adsorbed film and the lauric acid allowed to re-accumulate at the surface, by diffusion from the interior of the solution, have been determined by R. T. Florence, R. J. Myers and Prof. W. D. Harkins. They point out that possible variations due to the time factor must be taken into account when measuring the surface tension or surface potential of such solutions.

Research Items

Social Origins in India

Two things in the social organization of India immediately strike the observer, it is pointed out by K. P. Chattopadhyay (*J. Asiat. Soc. Bengal. Letters*, 1, 1935) in discussing peculiarities of caste in relation to early racial movement. One is the peculiar system of endogamy combined with exogamy running through the whole system, the other is that the giving of food and drink, or acceptance thereof, between different social groups depends on certain ideas of purity associated with the groups. In the course of further discussion, it is also noted that theories of caste, which have been put forward, tend to ignore local differences. Applying to conditions in India the results of an analysis of culture and the effects, issuing in rivalry and group isolation, presumably produced by racial migrations, it would appear that there were not two, but three cultured peoples who contended for mastery in India and built up the caste organization. Of two early streams of culture bringers one was a fisher folk, who were acquainted with, or later acquired, knowledge of iron and practised a rude form of agriculture, comparable to jhuming, but not terracing or systematic irrigation. Another people worked copper, silver and gold and practised terraced irrigation with hoe cultivation. Cattle were valued for meat only. A third stream of later date is associated with cattle for dairy work, but not for plough cultivation. This last-named employment of cattle is associated with another people, who sometimes preceded and sometimes followed the dairy folk. With this people and the people of the hoe cultivation is a tradition of origin from, or occurrence of, incestuous unions of brothers and sisters. The fisherfolk practised burial, at first in the house, but the hoe culture people practised cremation. In some instances the burial people, after being submerged, again recovered and then a formal, but not actual, cremation was made to precede burial. Alliances between different groups and bitter struggles appear to have taken place before equilibrium was reached and the caste system evolved.

Hormones and Evolution

In a communication recently presented to the Royal Anthropological Institute, Dr. S. Zuckerman discusses the evidence bearing upon the relation of hormones to the evolutionary problem (*Man*, 1936, August). How far, it is asked, is the endocrine system responsible for physical and psychological characteristics; what value is to be attached to Bolk's view of the endocrine mechanism as one through which man has become a fœtalized primate? Does the so-called hormone theory of evolution in fact reveal some novel evolutionary mechanism? Recent research has largely justified the *a priori* view that all the characteristics of the organism are moulded by an endocrine mechanism to subserve the developmental integration of the various bodily systems, in order that the correlated action of an organism as a whole should be possible. At the same time, physical and psychological characters are dependent on an enormous number of factors besides hormones. There is not the slightest direct experimental evidence in support of the view that different individuals and different racial types possess distinctive types of endocrine balance. We do not yet possess the data for making definite interpretations of racial types in terms of hormones. There is a correspondingly unfortunate lack of evidence in Bolk's view of the fœtalization of man, and within the order of primates an orderly process of fœtalization cannot be recognized. Yet it is not unlikely that human evolution may have proceeded by a series of changes in the endocrine complex; but we are defeated in any attempt to find in this conclusion some novel understanding of the evolutionary process. The endocrine complex, like any other character, is genetically determined, and we have no knowledge that the effect of its response to environmental influence is transmitted to a succeeding generation. The available facts of endocrinology provide no measuring rod by which to estimate the divergence between different racial types.

Sickness Absence and Labour Wastage in Industry

An attempt has been made by the Industrial Health Research Board of the Medical Research Council, by an investigation of data furnished by several organizations, to obtain some sort of datum line by which absenteeism due to sickness and wastage by lapsing from employment may be evaluated (Report No. 75. London: H.M. Stationery Office. 1*s*. 3*d*. net). This Report is divided into two parts, sickness being dealt with by May Smith and Margaret Leiper in Part i, and labour wastage by Major Greenwood and May Smith in Part ii. The measurement and incidence of sickness absence in clerical work and light organizations are considered, and in two large groups examined the rates for men are 3 days and 4½ days respectively, and for women 4 days and a little more than 6 days, per year. The crude rates obtained are subject to various fallacies, for example, long periods of absence due to serious illness of two or three workers may upset any simple arithmetical ratios obtained. Respecting labour wastage, the problem to be solved is discussed, the crude wastage rate is considered, and an 'industrial life table' is constructed. The actual labour wastage in two organizations is then studied, and various interesting features emerge from the analysis. Finally, suggestions are made for recording and analysing sickness absenteeism and labour wastage.

False-killer Whale in Scotland

Two papers dealing with the recent stranding of false-killer whales (*Pseudorca crassidens*) in Britain record an exceptionally interesting occurrence (*Scottish Naturalist*, 1936, p. 93). The greatest stranding, of forty-one individuals, took place in the Tay Estuary on November 27, 1935; but odd occurrences of single individuals or of small groups up to eleven in number which took place between November 16 and December 10, and ranged along the east coast from Norfolk to Montrose, show that a considerable movement must have been taking place in the North Sea. Prof. A. D. Peacock and his collaborators have recorded minutely the measurements and other striking characters, of the Carnoustie school of whales, reserving more detailed studies for later publication.

Hydroids from the West Indies

DR. EUGÈNE LELOUP in his monograph "Hydraires Calyptoblastiques des Indes Occidentales" (Mémoires du Musée Royal d'Histoire Naturelle de Belgique, Deuxième Série, Fasc. 2, 1935) describes collections made by P. Wagenaar Hummelinck on his voyage in 1930 to the West Indies, especially to the Islands Bonaire, Curaçao and Aruba. With these are specimens taken from floating Sargasso weed in the Atlantic and a series of calyptoblastic hydroids dredged at Dry Tortugas (Florida), the last sent by Dr. Waldo L. Schmitt, Smithsonian Institution, U.S. National Museum. Among these hydroids, four are found for the first time in the Atlantic : *Halecium dyssymetrum* from Florida, hitherto only known from the East Indies, and for the first time recorded since the type specimens were described; *Synthecium cylindricum* var. *pusilla* on Sargassum weed, previously known only from the Pacific ; *Laomedea kincardi* and *Sertularella minuscula* from Bonaire, previously known only from the Pacific and from the Indian Ocean respectively. Several other forms are reported for the first time since the discovery of the type specimens, and many are new records for certain localities. Among the fifty species and varieties described there are three new to science.

Principal Rots of English Oak

A SMALL volume on this subject by Messrs. Cartwright and Findlay of the Forest Products Research Laboratory has been issued by the Department of Scientific and Industrial Research (London : H.M. Stationery Office, 1936). Existing knowledge and recent work carried out at the Laboratory on the principal fungi causing decay in English oak are detailed and illustrated. One of the fungi attacking the tree is known as the beef-steak fungus, and the attack increases the value of the timber, producing the so-called 'brown oak' which fetches a higher price and is much valued in France. The report states that the general measures for controlling the attack of heart-wood of trees by fungi are the prevention, by sylvicultural methods, of the formation of large branches which may die by becoming infected with fungi. Attacks of this nature are serious in parts of England; but in some of the best managed oak forests in France are unknown. Probably one of the best preventives is to keep the young plantations dense and thin lightly in the earlier stages of growth; and to grow oak in mixture, preferably when possible with its natural companion beech. The economic aspects of the various rots of felled timber are dealt with ; and a final section treats of the stains and discolorations of oak wood such as 'golden oak', yellow, grey stains and chemical stain.

Composts for Mushroom Growing

THE food requirements of the common mushroom have not yet been determined with accuracy, though a considerable amount of success has been obtained with composts of a more or less synthetic nature. Mr. G. Paterson-Hart has described a number of such mixtures (*Gard. Chron.*, Aug. 1, 1936). Soya bean compost, a mixture of bean straw with tree leaves, and sphagnum moss impregnated with stable drainage, have proved fairly successful. Straw, covered with soil, and impregnated with salt solution, has grown mushrooms, whilst grass cuttings, ditch clearings, tree leaves and straw, when mixed and covered with mould, make quite a successful bed. The problem would seem to be to identify the common factor in all these different mixtures, and also in such varying habitats as stable sand dunes and heathy woods, where the fungus grows naturally.

Air Conditioning in Living Rooms

A SIMPLE device for humidifying air to a degree best suited for breathing has been developed by the A.E.G. Co. of Berlin and is described in *A.E.G. Progress*, No. 2, 1936. The water to be evaporated is contained in a tank in which rests a frame with capillary pads consisting of absorbent blotting paper overlapped and sewn together. These pads are completely saturated with water and can be readily replaced. The evaporation of the water is accelerated by an electric fan built into the back wall of the protective case. With a relative air humidity of 50 per cent and a temperature of 68° F., the apparatus evaporates about 7 oz. of water per hour. It is found that one filling of water is sufficient for eight hours operation. The quantity of water evaporated varies to a certain extent with the condition of the air, the rate increasing with the heat and the degree of dryness. The apparatus has been found useful in living rooms where the atmosphere gets close, in nurseries, in offices where smoking is allowed, as well as in hotels, hospitals, etc. In countries where a dry and warm summer climate has already rendered the electric fan indispensable, the apparatus is particularly useful, producing a refreshing and vitalizing effect.

The Nitrous Oxide Molecule

ALTHOUGH the molecules of carbon dioxide and nitrous oxide are both linear, it is known that one is symmetrical and the other unsymmetrical :

$$\mathrm{O} = \mathrm{C} = \mathrm{O} \qquad \mathrm{N} \underline{\leftarrow} \mathrm{N} = \mathrm{O}.$$

Cheng E. Sun and Ta-You Wu (*J. Chinese Chem. Soc.*, 4, 340 ; 1936) show that this difference may be explained by the energy contents of the two molecules. They used the semi-empirical method of Eyring and found that the unsymmetrical form of nitrous oxide has a lower energy content than the symmetrical form, whilst the reverse is the case with carbon dioxide. Although the method is only approximate, the differences between the energies of the two forms are sufficiently large to be significant.

Recent Advances in Enzyme Chemistry

IN a summary of recent work on enzymes, Prof. E. Waldschmidt-Leitz (*Chemistry and Industry*, 55, 620 ; 1936) points out that crystalline enzymes (urease, pepsin, trypsin, etc.) are all proteins, yet the reactions show that an enzyme cannot merely be a protein, the existence of a specific active grouping being necessary for enzyme differentiation. An iron porphyrin complex is the active group of liver and pumpkin catalases as well as of the peroxydase of horse-radish. A low molecular weight flavine compound, vitamin B_2, when connected with a protein carrier, becomes a true enzyme, the yellow respiratory ferment. The 'two-affinities' theory of von Euler, according to which an enzyme must be capable of reacting with its substrate at two distinct points in the molecule, is shown to be most defensible. The action of activators (for example, trypsin by enterokinase) is probably due to intermediate compound formation. Many other interesting features of enzyme chemistry are considered in the article.

Plankton Research

A SPECIAL plankton meeting was held by the International Council for the Exploration of the Sea in May 1935. The reports are published in vol. 95 of the *Proceedings* recently published. The papers by F. S. Russell and A. C. Hardy give an excellent picture of some aspects and methods of plankton research. H. Hoglund and S. Landberg report on investigations upon photosynthesis of phytoplankton by constant illumination, and B. Schulz on hydrographical problems.

In Russell's paper, all those studies of zooplankton are reviewed which are concerned with: (1) the distribution and abundance of the plankton in the open ocean and (2) in the coastal waters; (3) the relation of the animals with animate and inanimate environments and the causes of their fluctuation in abundance. A table based on data of various workers brings out facts of great interest, such as the greater number of cold-water species in the south as opposed to the north, the phenomenon of bipolarity of some planktonic species, the small number of purely subantarctic species of copepods, and differences between the faunas of the different oceans. The bearing of the plankton distribution upon the interpretation of hydrographical data is stressed. The author himself, in a notable study of the *Sagitta* population at Plymouth, has found that *S. elegans* is an indicator of Atlantic water and *S. setosa* of Channel water. Another important aspect dealt with is the relations between the plankton and the fish. "If correlations can be shown to hold consistently for a number of years it should be possible to predict certain conditions in the fisheries." Several other problems are discussed and attention directed to the need for further studies of life-histories and habits, food supply, and for more experimental work.

Hardy gives a preliminary account of experiments made by him and the research staff of the Oceanographic Department in Hull in the charting of the North Sea plankton. A new instrument has been used for the survey, the 'continuous plankton recorder'. This is an ingenious torpedo-shaped machine provided with a system of planes and a shock absorber, and inside with two bandings of filtering gauze arranged to wind off two rollers and to pass together into a tank of formalin. By means of a winding mechanism, for every mile of sea through which the instrument is towed a fresh section of gauze samples the plankton. Taken out of the preservative chamber, the number of organisms per division of silk can be estimated. With the co-operation of different steamship lines a programme of surveying was started in 1932. "The main objects of the survey are to chart the broad monthly changes in the density of the plankton along a series of lines across the North Sea . . . to correlate as far as possible the seasonal and yearly variations observed with changing hydrological and meteorological conditions on the one hand, and with fluctuations in the fisheries on the other, and in addition to provide extensive material for the study of ecological relationships between different members of the phyto- and zooplankton." Some promising examples of the results are given showing changes in the production of the phytoplankton and zooplankton in different seasons on the same line, and differences on different lines at the same periods.

B. Schulz reviews the results of hydrographical observations in the Kattegat in August 1931. Very numerous and detailed records were taken simultaneously during a week from five ships (one Danish, one Swedish, one Finnish and two German) lying within a relatively small area. The author summarizes the results as showing that "unperiodical changes of the hydrographical conditions (currents, temperature, salinity) at the points of observation were quite considerably bigger than one would have expected according to our previous knowledge and views. The mixing processes resulting in the Kattegat from the outflow from the Baltic Sea and the inflow from the North Sea are far more intensive and turbulent than was formerly supposed."

The Radio Exhibition at Olympia

THIS year's National Radio Exhibition at Olympia is the eleventh annual event of its kind, and the Radio Manufacturers' Association is to be congratulated on its successful organization of the show, which offered more comfort for the visitor than in the past, and also maintained the spirit of novelty which is so characteristic of this event. For the most part, the exhibition was a display of the vast variety of wireless receiving sets, which are now available to meet practically all the many and differing demands of the broadcast listening public. On a much smaller scale, the needs of the specialist and technically-minded enthusiast and experimenter are catered for, in the way of special components and of receiving sets for use abroad or for general experimental work. The impression was definitely conveyed that this vast industry of some twelve years standing is now firmly planted on its feet; with only a few exceptions, the names of the exhibitors are now almost common household words among the general public.

The general broadcast receiving set of to-day is similar in all essential features to its predecessor, various improvements in detail having been effected where in the past the control of the set has been difficult or inconvenient, or the performance has left something to be desired. It has undoubtedly improved in reliability due to the advanced testing methods adopted by the industry, and this is a feature that many members of the public will greatly appreciate.

The receivers now fall broadly into the two classes, comprising the straight amplifier and detector combination and the supersonic heterodyne type, and in each form separate models are generally available for either battery operation or for connexion to the electric supply mains. In one or two cases a spectacular method of visual tuning has been incorporated in the receiver. The great advance that has taken place in this year's sets, however, is the extension of the tuning arrangements to cover the short wave broadcasting bands. The title 'all-wave' tuning is generally applied to such receivers, but in only one or two cases can the set be tuned continuously from a wave-length in the region of 10–15 metres up to nearly 600 metres. The majority of the 'all-wave' receivers cover the short wave broadcasting bands only, there being gaps in the wave-length scale, where, at present, there are no transmissions of interest to the broadcast listener. Even with this restriction, however, it is necessary to provide the receiver with four separate wave-length bands, selected by an extension of the usual wave-change switch.

The production on a manufacturing scale of such a set in which the tuning on each band is controlled by the same knob, with a pointer reading on scales calibrated directly in wave-lengths, is a technical achievement of considerable merit. It is evident that, following upon the use of short-waves for Empire and other long-distance broadcasting, the reception of such short-wave programmes has now successfully passed beyond the experimental stage.

The other great feature of the exhibition was the demonstration of the present stage of television with the aid of the special test transmissions from the B.B.C. experimental station at Alexandra Palace. At this station separate television transmitters have been installed by the Baird Television Co. Ltd. and the Marconi E.M.I. Television Co. Ltd., and during the course of the radio exhibition these installations were used on alternate days for broadcasting a television programme. The accompanying sound was radiated from a separate transmitter installed by the B.B.C. The wave-lengths in use are 6·67 metres (frequency 45 megacycles per second) for the vision and 7·23 metres (41·5 megacycles per second) for the sound.

The daily programmes were received at the exhibition and demonstrated to the public on a number of receiving sets, the makers of which were not stated. Although naturally the interest displayed by large numbers of visitors precluded the study of the results for more than a short period, the demonstration was sufficient to indicate that the successful reproduction of a television programme broadcast from a station ten miles away is a present-day achievement. For the first time, the public has been enabled to see, as well as hear, the announcer in the studio and a well-known broadcasting singer. The majority of the programme comprised the transmission of sound-films, either constructed specially for this demonstration or extracted from standard news and entertainment films.

In the exhibition hall itself several firms displayed sets suitable for receiving these transmissions, although these were unpriced and were not in operation. The output on the vision side of these sets operates a cathode ray tube of unusually generous dimensions, the largest having a bulb of 22 inches diameter, the luminescent screen providing a picture area of 17½ in. × 13½ in. In most cases it is claimed that these receivers will give satisfactory results on the transmissions from the Alexandra Palace at distances up to 40 miles. In accordance with the recommendations of the Television Advisory Committee, all such receivers are arranged to reproduce the vision programme whether this be emitted on the Marconi E.M.I., or the Baird system.

It would thus appear that the time is ripe for the carrying out of practical and widespread tests of the possibilities of radio-television in Great Britain, although it is natural that some time must elapse before the technique has been simplified and the manufacturing costs reduced to such a point as to make television reception in the home available to the majority of the general public. R. L. S.-R.

Valency and Molecular Structure

By Prof. R. F. Hunter and Prof. R. Samuel

THE connexion between the numerical valency exhibited by an atom and the number of its outside electrons, which prevailed in certain pre-wave mechanical theories of valency and in the theory of Heitler and London, appears to us of fundamental importance to the problem. It cannot be fortuitous that iodine, for example, which possesses two *s*- and five *p*-electrons, exhibits odd covalencies of 1, 3, 5 and 7. Nevertheless, this relationship appears to have been lost sight of in the chemical theories of Lowry, Sidgwick, and others on account of the conception of co-ordinate covalency, in which only electrons belonging to one of the atoms concerned are made responsible for chemical combination. This conception appears to connect these theories with the theory of molecular orbitals (Herzberg, Lennard-Jones, Mulliken) in that chemical linkage is ascribed to the bonding power of single independent electrons, while the formation of pairs is an essential feature of the theory of Heitler and London.

Since valency is an ambiguous term, it is necessary to distinguish clearly between energetical questions and numerical chemical valency. While bond energy may vary from molecule to molecule, the valency number indicates the possibilities for chemical reaction and is a property of the free atom or radical. The maximal valency of the halogens is 7, but since this necessitates the fission of the s^2 group, considerable energy, which decreases with rise in atomic number, is required, so that heptavalency obtains with oxygen in Cl_2O_7 and with fluorine in IF_7. Although we are here mainly concerned with experimental facts, it is necessary to make brief reference to the wave mechanical interpretation of bonding power.

Wave Mechanical Considerations[1].—It is true that in the exchange integral (in formula 11 of Heitler and London's original paper),

$$E_{12}=\int\left(\frac{2\varepsilon^2}{r_{12}}+\frac{2\varepsilon^2}{R}-\frac{\varepsilon^2}{r_{a_1}}-\frac{\varepsilon^2}{r_{a_2}}-\frac{\varepsilon^2}{r_{b_1}}-\frac{\varepsilon^2}{r_b}\right)\frac{\psi_1\varphi_1\psi_2\varphi_2}{2}\,d\tau_1\,d\tau_2,$$

the attraction (negative sign) is produced by those terms which are caused by the terms of the potential representing interaction between one nucleus and one electron. The pure interaction between the electrons themselves (ε^2/r_{12}) gives an effect of opposite sign, and is antibonding. This, however, cannot be interpreted as proof of the bonding power of the single electron. That the whole expression E_{12} is called the exchange integral is not due to this term containing r_{12} representing the interaction of the electrons between themselves, but to the fact that the mere existence of the quantity E_{12} is connected with the use not of the wave function $\psi_1\varphi_2$, but of the wave function $\psi_1\varphi_2 \pm \psi_2\varphi_1$. This, in its turn, is the direct consequence of the degeneracy produced by the identity of the electrons.

Thus, the relation of the electron pair bond theory to the single electron bond theory in the method of molecular orbitals becomes quite clear. In the latter, the same terms appear even without the repulsion term with r_{12}, but the appearance of the double product $\psi_1\varphi_1$ is produced here not by the use of the function ψ_1 but of the function $\psi_1 \pm \varphi_1$. In other words, it is introduced by the identity of the nuclear fields.

From the point of view of a theory of valency, this is of course purely incidental. Chemical linkage is not confined to atoms of the same element, and attempts have therefore been made to explain this by means of a pseudo degeneracy of unequal nuclei, if the interaction is of the order $E_\psi - E_\varphi$, meaning that the valency of an atom not only as regards bond energy, but also in the numerical sense, should depend on the partner, and the greater the difference in the nuclear fields the smaller must be the distance between them to bring about this bonding effect.

The latter point is certainly empirically untrue as seen, for example, from the known diameters of oxides of the first short period. Regarding the first point, since we are not concerned here with the development of a perturbation method of calculation but with a theory of valency, it seems obvious that the valency number of an atom cannot depend on the partner with which it combines, other than in the energetical sense. Indeed the method of molecular orbitals gives incorrect results with regard to the products of dissociation of a molecule, due to neglect of the wave mechanical interaction of the electrons.

Since dissociation is the converse of molecule formation, this confirms our view that the method of molecular orbitals describes the electronic configuration and term system of the completed molecule but is not a theory of valency. Actually, it is unable to distinguish in itself between terms of attraction (molecule formation) and terms of repulsion (elastic collisions), and only becomes a theory of valency by the introduction of a postulate which identifies non-premoted with bonding electrons and premoted ones with anti-bonding. From new spectroscopical data it becomes increasingly evident, however, that this postulate can no longer be maintained.

Spectroscopical Evidence[1].—The number of molecules in which it is possible to correlate the molecular terms with those of the separated atoms has increased considerably of late. Particular interest is attached to the halides and oxides of the second group, in which it has been shown that the ground level of the molecule is correlated, not to an unexcited halogen or oxygen atom plus an unexcited metallic atom with the configuration $s^2\ {}^1S$, but to an excited metal atom with the configuration $sp\ {}^3P$. This now receives confirmation from some ten examples, the most striking of which are those in which the metal possesses high excitation energy. Whenever an excited molecular term appears in which the bond energy is higher than in the ground level, it is correlated to the so-called anomalous terms of the metal atom, in which both the original s-electrons have been simultaneously excited, showing that whenever a second linkage is formed (as in BeO and MgO), it occurs only in the presence of two p-electrons. Whenever an odd-electron molecule is formed (BeF and CaF), the partial removal of the odd electron increases the bond energy, showing that the unpaired electron is always disturbing.

Both these points receive confirmation from molecules of other types. NO, PO, and AsO, and also SiF and SnCl, all show the disturbing influence of the unpaired electron. On the other hand, molecules such as AlO and GaO are formed by the combination of oxygen with unexcited metal atoms of the configuration $s^2p\ {}^2P$, but the molecular term, of which the bond energy is much higher than in the ground level, is formed by the combination of oxygen with metal atoms of the configuration $sp^2\ {}^4P$; the second linkage again occurring only after fission of the s^2 group. These results are incompatible with the theory of the co-ordinate link and show the antibonding character of the closed helium-like s^2 group, which constitutes the 'lone pair' in the majority of cases. While the pair bond conception of valency gives a straightforward and consistent interpretation of these results, the theory of molecular orbitals, on account of its premotion postulate, would predict that molecules such as BeO and BeF would be formed by unexcited metal atoms because they possess an excess of non-premoted (and therefore bonding) electrons.

The difference between an electron pair bond theory of valency and that of molecular orbitals finally finds its expression between localized and non-localized electrons in polyatomic molecules. The first experimental evidence in this connexion has been obtained from a complete vibrational analysis of the band spectra of SO_2 and SeO_2. These results show that the harmonic vibrations, for example, of SeO in its unexcited and excited states, agree closely with two symmetrical valence vibrations of unexcited and excited SeO_2; the energy of electronic excitation being almost identical in the two molecules and the factor of anharmonicity of the ground states, which could not be accurately determined for SeO_2, appears at least to be of the same order. Furthermore, the heat of dissociation of SeO_2 into gaseous atoms is about twice that of SeO. The molecular constants of SO_2 bear the same relationship to those of SO, and the continuous absorption spectra of halides and oxyhalides of sulphur show that the bond energies of the S–Cl, S=O, and S=S bonds are approximately of the same order in widely differing molecules such as SO, SCl_2, $SOCl_2$, S_2Cl_2, and SO_2.

Each of the bonds in polyatomic molecules of this type appears to be localized between two atoms, in accordance with the older structural formulæ of chemistry. It is characteristic that there is one atom which may be regarded as the central atom, and for such cases the Heitler-London theory indicates strong localization of bonds.

Chemical Evidence[3].—It has been shown that the conception of the lone pair of electrons as an agent for true chemical linkage is in direct contradiction to the results of band spectroscopy. In our opinion, the spectroscopical evidence is of the greatest importance for the following reasons. The difference between two non-electrostatic links (normal and co-ordinate covalency) involves a difference of the role played by individual electrons. Physico-chemical measurements such as the parachor, dipole moment, etc., are concerned with the whole electronic cloud of valency electrons, and *a priori* cannot give information as to the part played by a particular electron. This can only be obtained from spectroscopical experiments. It is therefore always possible to interpret the mechanism of chemical linkage from the results of physico-chemical experiments in alternative ways, as has already been indicated in cases of the parachor, optical activity (for example, toluene-sulphonic esters and beryllium benzoylpyruvate), and crystal structure (SiF_6^{--}).

Similarly, the increase in dipole moment accompanying the formation of certain molecular associations in solution observed by Earp and Glasstone[4] is no proof of the presence of a co-ordinate link. The dipole moments of such associations sometimes decrease and sometimes increase, depending on the geometrical position of the constituent molecules as to whether there is a cancelling out, or an increase through induction[5]. The energies of dissociation of such complexes, determined by these and other authors, vary between 1 and 10 k.cal./mol., which is about 1/100 to 1/10 of that associated with a true chemical bond. This, in our opinion, proves conclusively that the complexes are loose associations held together by van der Waals forces.

With regard to the resonance linkage suggested, for example, for the NO_2 group, it is possible that a co-ordinate link would oscillate between the oxygen atoms if it existed, but no experimental proof has so far been advanced for its existence. These arguments therefore in no way invalidate our earlier conclusion that chemical and physico-chemical evidence fail to provide any proof for the existence of a second form of non-electrostatic linkage in molecules of the first order.

It is true that an atom possessing a lone pair of electrons is frequently associated with chemical reactivity in carbon chains and the formation of complex associations in inorganic chemistry. Since band spectroscopy excludes a mechanism of the 'donor' and 'acceptor' type, something else must be responsible for such phenomena. As a tentative suggestion, it may be pointed out that the molecular refractivity indicates that the polarizability is always high in such atoms so long as the electrons of the lone pair are not involved in chemical linkage, and that the large dipole moment induced on approach of a reagent molecule might be responsible for such phenomena.

We wish to express our gratitude to Prof. F. London for his help in connexion with the wave mechanical section of this article.

Science News a Century Ago

Death of John Pond, F.R.S.

ON September 7, 1836, John Pond, the sixth Astronomer Royal, died at Blackheath at the age of sixty-nine years, and a few days later was buried in the tomb of Halley in Lee churchyard. Pond was born in London in 1767. After attending schools at Hadleigh and Maidstone, at the age of sixteen years he entered Trinity College, Cambridge, and attended the mathematical lectures of Vince. Ill-health led him to travel, and during visits to Portugal, Malta, Turkey and Egypt he made many astronomical observations. From 1798 until 1807 he lived at Westbury, near Bristol, where by his observations on the declination of some of the principal stars he showed conclusively that Bird's quadrant at Greenwich had altered its form.

Pond was elected a fellow of the Royal Society in 1807. He married and removing to London in 1811 was chosen to succeed Maskelyne at the Royal Observatory. In 1812 he mounted a six-foot mural circle by Troughton, in 1816 a transit instrument of 5-in. aperture, in 1821 substituted the mercury horizon for the plumb-line and spirit-level, and in 1825 introduced the system of observing the same object by direct and reflected vision. A sound practical astronomer, he published catalogues of stars, translated Laplace's "Système du Monde" and wrote many articles for Rees' "Encyclopædia". In 1817 he was awarded the Lalande Medal and in 1823 the Copley Medal. He was succeeded at Greenwich by Airy, who, writing to Henry Warburton, M.P., to support an application for a pension for Mrs. Pond, said that Pond's claims to the gratitude of astronomers were due first to the accuracy which he introduced into all the principal observations, secondly, to the attention he bestowed on those points (chiefly of sidereal astronomy) which he regarded as fundamental, and thirdly his regularity of observation. "Since the commencement of Mr. Pond's residence at Greenwich," said Airy, "Astronomy considered as an accurate representation of the heavens in the most material points has acquired a certainty and an extent which it never had before."

Discovery of Fossils on the Continent

IN its column of Miscellanea, the *Athenæum* for September 10, 1836, said: "Dr. Klippstein, a German savant, who has been long devoted to geology, and who directs the researches in the environs of Alzei (a little town of the Rhine Hesse) has lately made a discovery. On digging twenty-eight feet under the soil, near Eppelsheim, and a league from Alzei, his workmen found a head of a Dinotherium giganteum, in perfect preservation. This is probably the most colossal of all antediluvean animals, and the existence of which was first pointed out by the learned zoologist, Dr. Caup. This head is six feet long and three feet and a half broad. Near the head was also found a shoulder bone of which remains have not been met with elsewhere. Also at one thousand feet below the surface, in the mines of Anzin, an entire fossil palm tree has been found in an upright position. Its roots pierced the soil to a depth of several feet, and it is to be brought to the Museum of Natural History in the Jardin des Plants."

The neighbourhood of Mainz and Alzey early attracted the attention of geologists on account of its wealth of fossils. Von Zittel said: "The discovery of the famous Dinotherium skull at Eppelsheim by Klipstein and Loup induced Klipstein to contribute a more careful stratigraphical account of the strata in the Mainz basin, and he paralleled the bone-bearing sands of Epplesheim with the gypsum of Montmartre, and the limestone strata under the bone-bearing sands with the coarse limestone beds of Paris."

Yarrell's History of British Fishes

Among the books on natural history published in 1836 was the "History of Fishes" by William Yarrell (1784–1856), an original member of the Zoological Society and at one time treasurer to the Linnæan Society. In a review of his work in the *Athenæum* of September 10, 1836, it was said the book was "intended to form a continuation of Bewick, whose beautiful woodcuts, occasional vignettes and *naive* descriptions will ever be ranked among our standard works . . . and we can safely say, to all those who possess Bewick's works, that their collection is not complete without adding Mr. Yarrell's fishes to the birds and beasts.

"The description of species are 226 in number, but as several of them are figured in various stages of growth, the representations amount to 240—all made under the superintendence of the author; besides which there are more than 140 vignettes of modes of fishing, boats, nets, etc., foreign and English."

Societies and Academies

Paris

Academy of Sciences, July 15 (*C.R.*, 203, 137–216).

Gabriel Bertrand and Louis de Saint-Rat : A new colour reaction of copper with urobilin. This reaction is more sensitive and more specific than other reactions in use for the detection of traces of copper. 0·0001 mgm. of copper in 1 ml. of solution can be detected with certainty.

Gabriel Bertrand : Pentacetylxylite. Details of the preparation and purification of the acetate.

Robert Lespieau : The synthesis of *r*-arabite.

Serge Bernstein : Some extremal properties of successive integrals (correction).

Charles Pisot : Certain characteristic properties of algebraic numbers.

Farid Boulad Bey : The canonical forms of equations of nomographic order 6 and 5 representable by nomograms with symmetrical scales.

Christian Pauc : Directions, contingent and paratingent in *distanciés* spaces.

V. A. Kostitzin : The differential equations of the problem of Mendelian selection.

Gino Arrighi : The expression of the energy of acceleration.

Jean Jacques Trillat and Mlle. Renée Vaillé : The unctuosity of mineral lubricating oils.

Mme. H. Emmanuel-Zavizziano and M. Haissinsky : The electrolysis of solutions of titanium salts. By varying the conditions of the electrolysis, compounds of Ti'', Ti''', Ti'''' and of pertitanic acid can be prepared.

Michel Kantzer : The optical absorption of the vapours of tellurium dichloride and oxychloride.

Pierre Lambert and Jean Lecomte : Description of a recording spectrometer with a grating and its use for the determination of the absorption spectra of benzene derivatives in the 3000 cm.$^{-1}$ region.

Augustin Boutaric and Jean Bouchard : Study of the fluorescent power of some fluorescent solutions excited by ultra-violet rays.

Mlle. Yvette Cauchois : Study of the L spectra of emission and absorption of rhenium (75) I.

Marcel Lecoin : The form of the continuous β-spectrum of radium E. The method was based on the use of a Wilson chamber placed in a magnetic field. The results are given as a curve, and differ considerably from the values found by the method of coincidences.

Charles Haenny : The secondary radiation emitted under the action of neutrons.

Maurice E. Nahmias and Robert J. Walen : Some short periods in artificial radioactivity.

Henri Muraour and Gabriel Aunis : The laws of combustion of colloidal [explosive] powders.

Mlle. Niuta Klein : The transformation in glass.

Mlle. Valerie Deutsch : The absorption of proteins. Crystallized hæmoglobin from the horse.

Edouard Rencker and Pierre Dubois : The hydrates of manganous sulphate. The only definite hydrates are those containing 7, 5, 4, 3 and 1 molecules of water.

Alfred Maillard : The system monomethylamine-calcium chloride.

Maxence Meyer : A new method of preparation of the diethoxysuccinic esters.

Léon Enderlin : Contribution to the study of the reversible oxidizability of organic compounds. Iso-oxybis-*p*-bromphenyldiphenylnaphthacene.

Léon Denivelle : The sulphate of *o*-phenylene or sulphurylpyrocatechol.

Charles Courtot and Mohammed Gholi Bastani : Introduction to the study of the chemistry of diphenylene telluride.

Mlle. Berthe Delaporte : Cytological researches on the group Coccaceæ.

William Henri Schopfer : Researches on the nitrogen metabolism of a micro-organism.

Charles Chabrolin : The germination of the seeds of the orobanche bean (*Orobanche speciosa*). The substance which induces the germination of the seeds of the orobanche bean diffuses round the roots of certain plants and can be washed out with water.

Paul Bertrand : The embryos of angiosperms, ferns and lycopods.

Francois Rathery, André Choay and Pierre de Traverse : The comparative action of insulin and of the hypoglycæmic principle of the jejunum in the depancreated dog.

Raymond-Hamet : A new method of showing sympathicolytic power.

Gustave Guittonneau and René Chevalier : The utilization of salicylic acid as an energy producing food by *Azobacter* in the soil.

Anthelme Rochaix and Pierre Rivollier : A dissociation of the staphylococcus.

Washington, D.C.

National Academy of Sciences (*Proc.*, 22, 327–434, June 15).*

David I. Macht and Raymond E. Gardner : Phytopharmacological reactions of normal, toxic and atoxic sera. The phytotoxic index is defined as the ratio of the rate of growth in the dark for 24 hours at 12° C. of roots of seedlings of *Lupinus albus* immersed in a solution to be examined to the rate

* *Continued from p.* 378.

of growth of controls in a nutrient solution under the same conditions. Normal human blood and blood sera from a number of animals gave an index averaging 75 per cent. Reptilian blood was very toxic, as was also that of sera from cases of pernicious anæmia, pemphigus and leprosy. Virus diseases gave sera less toxic for plant growth than normal blood sera.

Albert W. Hull: Changing direct current to alternating current by means of thyratrons. Constant voltage 3-phase A.C. was changed to constant current by a 'monocyclic network' of capacitors and reactors. This current was converted by a conventional circuit of radio type into a constant direct current. The direct current is changed back into alternating current by an exactly similar circuit, with thyratrons in place of rectifiers. Special tubes were developed for the purpose, and in a circuit described, 15,000 volts at 200 amp. peak is rectified to 200 amp. at 30,000 volts D.C., and the latter 'inverted' to alternating current.

Francis G. Benedict and John M. Bruhn: Chimpanzee metabolism. Twenty-two animals ranging in age from two months to fifteen years were used. Respiratory exchange was measured with an open-circuit respiration chamber, the out-coming air being sampled. The average heat production of a chimpanzee per 10 × $w^{2/3}$ (where w is weight), ranges around 1,000 calories. Unlike man, it is not unusually high in infant and pre-adolescent years.

C. P. Haskins and E. V. Enzmann: A determination of the magnitude of cell "sensitive volume" associated with the white-eye mutation in X-rayed *Drosophila* (2)

C. P. Winsor and Anna-Betty Clark: Dark adaptation after varying degrees of light adaptation. The shape of human dark adaptation curves changes with the degree of initial light adaptation. The results are consistent with Wald's view that three substances are involved in the visual purple cycle.

Francis G. Benedict and Robert C. Lee: Studies on the body temperatures of elephants. The temperature of urine taken immediately it was voided averaged 35·9° C.; that of the fæces was 0·7° C. higher, due to fermentation. The elephant thus has the lowest body temperature of any of the large animals (man 37° C., birds 42° C.).

Morgan Upton: Differential sensitivity in sound localization. When the two ears are stimulated by equal energies at 800 cycles, the apparent sound is localized in the median plane of the head. The ratio of energy increment required to produce a noticeable shift of localization to original energy is large for low levels of energy, small for intermediate levels and increases again for very high levels. The results cannot be described in terms of the Weber-Fechner law.

W. J. Crozier: On the sensory discrimination of intensities. The increment of light intensity which is just detectable is variable and should be treated statistically. The relation of sensory intensity (effect) to stimulating intensity should be discussed as a 'band' which measures the probability of occurrence of the index response.

Morgan Upton and W. J. Crozier: On auditory intensity discrimination. A theoretical discussion of Upton's results (above). The energy increment involved can only be regarded as related to the mechanism of excitation so long as its statistical character is recognized.

J. van Overbeek: Light growth response and auxin curvatures of *Avena*.

James Bonner: Plant tissue cultures from a hormone point of view. Parenchyma tissue from the lining of the 'cups' left when immature seeds are removed from bean pods has shown cell elongation and cell division *in vitro* in a culture medium to which an alcohol extract of fresh beans was added. The cell mass continued to grow as parenchyma, and a limited number of sub-cultures could be made, but from the central tissue only. Some chemical properties are given of the factor which seems to make growth possible.

Carl Iver Hovland: 'Inhibition of reinforcement' and phenomena of experimental extinction.

Kenneth W. Cooper: Demonstration of a hatching secretion in *Rana pipiens* Schreber. The jellies and vitelline membranes of early tail-bud larvæ were removed, and the freed embryos were kept in water until normal embryos of similar age had hatched. The contents of dishes containing free embryos were filtered and the filtrate centrifuged and decanted. This liquid was able to remove the jellies from fertilized eggs, etc., the vitelline membrane swelling away from the egg or rupturing, at stages when manipulative removal is very difficult.

Vienna

Academy of Sciences, June 12.

Jovan Jurišić: Morphology and biology of *Bryophyllum Daigremontianum* (Hamet and Perrier de la Bâthie).

Heinz Horninger: Geometrical theory of reflection at curved surfaces.

Walther Ruziczka: Accumulation of iodine by cumarin derivatives.

Leopold Schmid and Hugo Körperth: (1) The colouring matter of the poppy. (2) Extracts of petals.

F. Wessely, A. Münster, and K. Schonol: The bitter principle of Columbo wood. (4). Hydration of columbin and isocolumbin.

Richard Schumann: The moon, sun and variation of latitude (2).

Otto Redlich, Trude Kurz and Walter Stricks: Raman spectra and constitution of hexabromostannic ion and hypophosphite ion. The occurrence of five fundamental frequencies in its Raman spectrum shows that the hexabromostannic ion has D_{4h} symmetry.

O. Friedrich: Geology of the gravel bed of the Gross-Arl valley.

Elfriede Eysank: Coloration of fluorite and rock salt. Fluorite has an absorption band between 575 and 650 mμ and another between 380 and 405 mμ. The properties of these two bands are studied.

Irmberta Leitner: Quantum yield in the coloration of rock salt by X-, γ-, and β-rays. X-rays produce 10^4–10^5 and β- or γ-rays 10^2–10^3 colour centres per quantum. High energy quanta probably act through the secondary radiation they produce.

E. Guth and S. Rogowin: Mechanical properties of threads and films of cellulose derivatives.

Karl Schwarz and Franz Ebster: The possibility of producing multiply ionized atoms of very high energy.

O. Brunner and W. Kleinau: Visual purple (2). Mechanism of the bleaching process.

Friedrich Hartmann: The most general case of breaking of rods of structural steel.

Forthcoming Events

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE (BLACKPOOL MEETING).

Wednesday, September 9

At 8.30 p.m.—Sir Josiah Stamp, G.C.B., G.B.E.: "The Impact of Science upon Society" (Presidential Address in the Empress Ballroom, Winter Gardens).

Thursday, September 10

At 10 a.m.—Prof. J. C. Philip, F.R.S.: "The Training of the Chemist for the Service of the Community" (Presidential Address to Section B, followed by a discussion).

Dr. J. S. Huxley: "Natural Selection and Evolutionary Progress" (Presidential Address to Section D).

Brigadier H. S. L. Winterbotham: "The Mapping of the Colonial Empire" (Presidential Address to Section E).

Prof. W. Cramp: "The Engineer and the Nation" (Presidential Address to Section G).

Miss D. A. E. Garrod: "The Upper Palæolithic in the Light of Recent Discovery" (Presidential Address to Section H).

Mr. J. Ramsbottom: "The Uses of Fungi" (Presidential Address to Section K).

Sir Richard Gregory, Bt., F.R.S., Prof. L. Hogben, F.R.S., S. R. Humby, S. V. Brown, Sir Daniel Hall, F.R.S.: "Cultural and Social Values of Science" (Discussion: Section L).

Sir John Orr, F.R.S., Sir Daniel Hall, F.R.S., Prof. J. A. S. Watson, Prof. H. D. Kay: "National Nutrition and British Agriculture" (Discussion: Section M).

At 2 p.m.—Conference of Delegates of Corresponding Societies. Dr. A. B. Rendle, F.R.S.: "Preservation of Native Floras" (Presidential Address).

At 4.30 p.m.—Exhibition of new Biological Films.

At 7.30 p.m.—Dr. Olaf Bloch: "The Scope of Photography" (Public Lecture at Lytham St. Annes).

Friday, September 11

At 10 a.m.—Prof. A. Ferguson: "Trends in Modern Physics" (Presidential Address to Section A).

Dr. C. R. Fay: "Plantation Economy" (Presidential Address to Section F).

Prof. R. J. S. McDowall: "The Control of the Circulation of the Blood" (Presidential Address to Section I).

A. W. Wolters: "Patterns of Experience" (Presidential Address to Section J).

Sir Richard Livingstone: "The Future of Education" (Presidential Address to Section L).

Denys W. Harding, F. C. Thomas, Rev. F. A. Farley: "The Psychology of Mass Entertainment" (Discussion: Section J).

At 2.15 p.m.—Prof. H. J. Fleure, F.R.S., Dr. J. S. Huxley, Dr. G. M. Morant, Prof. A. M. Carr-Saunders, Prof. R. Ruggles Gates, F.R.S., Prof. F. A. E. Crew: "Genetics and Race" (Discussion: Sections D and H).

At 7.30 p.m.—Dr. W. F. Bewley: "Science and the Glass-house Industry" (Public Lecture at Blackpool South).

At 8 p.m.—Prof. J. L. Myres: "Who were the Greeks?" (Public Lecture at Preston).

Sir James Jeans, F.R.S.: "Some Recent Advances in Astronomy" (Public Lecture at Southport).

At 8.15 p.m.—C. C. Paterson: "Science and Electric Lighting" (Evening Discourse).

Science and the Community

CENTURIES of tradition and experience have given us, as Prof. A. N. Whitehead has pointed out, a tradition that each generation will live substantially amid the conditions governing the lives of its fathers and transmit those conditions to the succeeding generation. In his words, "we are living in the first period of human history for which this assumption is false". The time span of important change no longer exceeds considerably the normal span of human life, and we have now to meet change as the normal—not the exceptional—experience.

This necessity for change has at least two aspects. It involves the modification of man's nature to meet the new conditions, a re-adaptation to his environment. It also involves the modification of his existing social, economic, political and industrial organization and institutions to meet the requirements of an era of power production and rapid change, or the evolution of new forms of organization where the old prove inadequate and incapable of development.

The seriousness of the present international situation, no less than our economic difficulties, is largely due to the failure to face change and adapt institutions to meet it. In the Fascist and totalitarian State there are deliberate attempts to put back the clock and return to a simpler order of society, creative thought and adaptability being repressed in an attempt to maintain institutions evolved in a pre-industrial era. Simultaneously, in the assumed defence of the State, the full resources of a power production era are being marshalled for destructive purposes.

On the scientific side, even though in the training of the man of science there is still no concern with the social consequences of his work, scientific workers are to an ever-increasing extent turning their attention to such matters. In the five years since, in his presidential address to the British Association, General Smuts directed attention to the dangers arising out of rapid scientific advance as opposed to a stationary ethical condition, the relations between science and society have been considered on an increasing scale at the British Association meetings both in the presidential addresses and in sectional meetings. Two years ago, the Council suggested in a memorandum to the organizing committees of the various sections that discussions, papers or symposia should be included in their programmes bearing upon the relations between the advance of science and the life of the community.

The attention given to this subject in the programme of the present meeting is fully as great as in previous years. Discussions on chemistry and the community, cultural and social values of science, national nutrition and British agriculture, the psychology of mass entertainment, the reform of the examination system, the poultry industry, traffic safety, chemistry and food science, the strain of modern civilization, and addresses on the engineer and the nation, soil science in the twentieth century, etc., indicate over how wide a field scientific workers are seeking the solution of problems of social well-being and the interpretation of the results to the general community.

It is not on this account alone, however, that the impact of science upon society forms most appropriately the main theme of this year's presidential address. While more scientific effort than ever before is probably being devoted to the elucidation of social problems and the interpretation of the results to the community, there has never been more general alarm about the possibilities of the application of the results of scientific discovery or greater willingness to endorse the late Sir Alfred Ewing's words: "The command of Nature has been put into man's hand before he knows how to command himself."

For this uneasiness the rapid deterioration in international relations during the past year, the weakening of international co-operation and the grim menace of re-armament have been largely responsible. In the growing effort being devoted to preparation for warfare, it is easy for the possibilities of a higher standard of living which science has placed within our grasp to be overlooked, and for the scientific worker to be associated rather with the perversion of his knowledge for destructive purposes. Again, the intensification of preparation for self-defence has tended to strengthen the fetters on freedom of investigation and exposition which dictatorships in many countries have already riveted on industrial and academic workers alike.

The growing impatience of the scientific worker at the extent to which his knowledge is made to serve inhuman ends finds admirable expression in Prof. J. C. Philip's presidential address to Section B (Chemistry) and is paralleled by the alarm at the continued threat to academic freedom and scientific research itself which, as the University Grants Committee pointed out in its report, lays a heavy responsibility on the universities of Great Britain if the Greek tradition of candid and intrepid thinking about the fundamental issues of life is to be preserved for mankind.

Sir Josiah Stamp, in his presidential address to the Association, which appears elsewhere in this issue (p. 435), has thrown down a challenge to creative thought on the impact of science upon society and the technique of change it involves, which comes at an opportune moment. The development of economic planning on a larger scale has made it painfully evident how the full effects of the wisest schemes may be neutralized by factors outside their control. Only by the widest co-ordination can the fullest benefits be secured, whether within the limits of an industry or of a national unit. The resistance of institutions to change not only increases the friction and makes change more difficult and the application of science less profitable and less readily accepted; it also tends to throw out of ratio what Sir Josiah Stamp has termed the scientific, industrial and political periods of gestation.

The present tendency is for the period of scientific gestation, or the interval between the first concept of the idea and its publication in substantially the form in which it is ultimately used extensively, to contract. It is even more demonstrable that industrial gestation, or the subsequent interval between this point and the time when the innovation becomes effective in an economic or industrial sense, has shortened materially and at greater social cost. This contraction is attributed to the greater amenability of the industrial community to scientific research and to our entering on an epoch of concerted industrial research in the last twenty years.

It is to the third question, that of political gestation, that Sir Josiah Stamp directs particular attention. Formerly, the normal span of life of man and machinery provided a phase to which scientific advance could be adjusted for a completely smooth social advance. Technical changes now occur so rapidly that political institutions work far too slowly to make the required adaptation. Political gestation is a function both of human psychology and of social structure, and at present we do not know enough about the way in which ideas permeate, infiltrate or saturate society.

While to prevent disequilibrium it is necessary to evolve some means of contracting the period of political gestation, some of the factors which hitherto have diminished the force of impact on society are losing their previous force. Among such, Sir Josiah Stamp cites the natural increase of population, which is disappearing in all Western industrial countries, and the labour demands of new industries, which offset dislocations caused by labour-saving machinery.

If, therefore, the risk of innovation becomes mechanically rapid, the danger of improvident tardiness is the more acute, and it becomes essential to treat on scientific lines those questions of man's abilities, his affections and his tools which have been brusquely dismissed in the past. With the intensification of scientific effort and the greater subdivision of industry, the possible dislocation becomes more frequent and the way of meeting such change of greater public importance. Impact and change must, in fact, be treated as an area for scientific study, and society must endeavour to regulate the rate of change to an optimum point in the net balance between gain and damage.

No scientific worker can fail to recognize the practical difficulties of economic and political prevision, as involved, for example, in Sir James Irvine's plea for a Ministry of Knowledge for the purpose of predicting the repercussions of new knowledge on all phases of life. None the less, a deliberate attempt may yet have to be made. Moreover, it is clear that the moral and social consequences of innovation, no less than the material, must be taken into account in our calculations, and it may even be desirable to repress the rate of development on the physical side in order to accelerate assimilation on the moral and human aspect. Birth control, for people, may yet demand corresponding measures for their impedimenta.

Sir Josiah Stamp adds one more voice to those which in recent years have pleaded for redistribution of scientific effort and resources. There is not too much effort being devoted to research in physics and chemistry as modifying industry, but there is too much relatively to the research upon the things they affect in physiology, psychology, economics, sociology. Additional financial resources should be applied more to the biological and human sciences than to the applied physical sciences or, if resources are limited, transfers should be made from one to the other.

What is required is not less science but a great extension of the area to which the scientific method is persistently and dispassionately applied. This is no time for a spirit of defeatism but for fuller support of those means of acquiring knowledge on the human and biological side where it is at present deficient. We must achieve an advance in the science of man commensurate with that which we have already secured in the science of matter.

For this task there are two essentials—a time of peace in which the problems can be effectively studied and the adjustments made, and courage and confidence strengthened by the conviction that the human spirit is not doomed to relapse into barbarism, but is fully as capable of emerging from an age of mechanization and standardization to one in which the teeming units of mankind enjoy not merely physical comfort and adequate leisure but also freedom of access to all the rich heritage of civilization. If scientific workers are stimulated by the presidential address and other discussions at the Association's meetings to make more constructive contributions to this question of peace and the impact of science upon society, the Blackpool meetings may well be memorable in annals wider than those of science alone.

Geophysics of the Indo-Pacific Region

Geographie des Indischen und Stillen Ozeans
Im Auftrage der Deutschen Seewarte verfasst von Prof. Dr. Gerhard Schott. Mit einem Beitrag von Prof. Dr. Ernst Hentschel und Dr. Wolfgang Schott. Pp. xx +413 +38 plates. (Hamburg: C. Boysen, 1935.) 36 gold marks.

EVER since Prof. G. Schott, ten years ago, published his great work on the geography of the Atlantic Ocean, geographers and oceanographers have been eagerly awaiting the companion volume on the Indo-Pacific region. In the present work the author has followed the same original plan and, commencing with a historical account of the discovery and exploration of these two oceans, he brings under review the whole sum of our present knowledge, ranging from the geological character of the coasts, through the topography and nature of the sea-floor, the meteorological conditions, the current systems and the physico-chemical character of the sea-water from the surface down to the great depths in the various regions into which these two oceans are divided, to the biological conditions present, including in this latter topic a survey of the anthropology of the whole area.

In his historical account of the great explorers, who opened up for us these wide spaces, Schott mentions the name of Francis Drake in a footnote and in his chart only shows him as having visited the west coast of America, whereas he also sailed the Malay seas, visiting Java and the Moluccas, and was in all probability the first to discover the Giant Robber crab (*Birgus latro*) and to note its habit of living in colonies and of climbing trees.

One great difficulty, which confronts all oceanographers, is the uncertainty of the mode of origin of the great oceans, and this applies especially to the northern part of the Indian Ocean, regarding which one school of geologists holds that it has been formed by the foundering of a great continent, Gondwanaland, while another school believes with Wegener that the oceans have been formed by a gradual drifting apart of the present continental masses. Schott apparently belongs to the former school, and he describes how Africa, Arabia and India are all stable land-masses that are bounded by scarp-faults, where the hypothetical continent of Gondwanaland, that once connected them, has broken off and subsided; it is to this permanence of these land-masses that Schott attributes the apparent comparative freedom of the Indian Ocean from volcanic islands, though, since we are as yet completely ignorant of the geological nature of the basis on which the Laccadive, Maldive and Chagos archipelagos rest, this freedom may be more apparent than real. Down the whole length of the Indian Ocean and across the south-eastern part of the Pacific Ocean two great submarine ridges have now been traced, the two together forming an almost complete semicircle that runs around nearly half the circumference of the globe; but wherever these ridges rise above sea-level, or fragments of rock have been obtained from the sea-floor along their length, the rock has been found to be volcanic in origin and is composed of basalt, thus giving no indication of its geological age; and Schott is thus scarcely justified in claiming that the recent John Murray Expedition, which in 1933–34 mapped a great part of the Carlsberg Ridge and discovered a subsidiary ridge running up towards and probably representing a submarine continuation of the Khirtar Range of India, has thus provided further evidence of the former existence in Permo-carboniferous times of Gondwanaland, or even of its later relic, the isthmus of Lemuria.

In discussing the great 'deeps' that almost invariably lie close to the eastern side of a continental land-mass, Schott reviews the possibility that these have been produced by either faulting or folding, but he makes no mention of the alternative theories of isostatic adjustment or of continental drift.

In his account of the currents, both surface and deep, Schott brings out clearly the enormous importance of the correlated study of the general meteorological conditions; evaporation and solar radiation produce differences in density of the water, thus inducing sinking of water-masses downwards, while the prevailing winds, by inducing horizontal movement of the surface-water in different directions, cause the zonation of the great oceans into tropical, sub-tropical and polar regions, separated from one another by 'convergence zones', along which one mass of water is driven beneath another and sinks down to a deeper level, thus causing a stratification of the ocean into depth-zones, in which temperature, salinity, oxygen content, etc., are sufficiently different to enable us to trace the course of the deep currents and thus discover the manner in which the deeper waters of the Atlantic and Indian Oceans sweep eastward to the south of the continental masses of Africa and Australia and flow into the Indian and Pacific Oceans respectively. Similarly, the Trade winds, by setting up off-shore currents, cause an up-welling of deep cold water that has a profound influence on the character of the fauna and flora, one notable effect of such up-welling being the absence of coral reefs even in tropical regions, as, for example, on the western coasts of Africa and South America or the south-eastern coast of Arabia and the neighbouring coast of Africa. Yet off the north-western coast of Australia, where the conditions would appear to be favourable to its formation, such up-welling appears to be absent.

The zonation of the surface water has, at any rate in certain regions, a profound influence on the character of the sea-bottom, for, as Schott points out, there is a close agreement between the south polar convergence zone and the change on the sea-floor from the tropical and sub-tropical Globigerina ooze to the polar Diatom ooze, and, to a less degree, the same holds good for the north polar convergence zone. It is, however, difficult to understand how this agreement is brought about, for it is now well known that the polar water, characterized by a profusion of diatom growth, dips at the convergence zone downwards under the sub-polar water and flows northwards towards the equator, and one would have expected this Antarctic Intermediate Current to carry the slowly sinking frustules of the diatoms far to the north; but for some reason not yet understood the convergence zone appears to mark, not only a change in the surface conditions, but one also in the general character of the plankton at all depths.

Another problem connected with the sea-floor is the mode of formation of the Red Clay that covers vast areas of the north and south Pacific regions and the eastern part of the Indian Ocean. The conditions favouring its formation appear to differ radically in these areas and in the Atlantic, for in this latter ocean the Red Clay is deposited where the Antarctic Bottom Current is strongest, whereas in the Pacific the reverse seems to be the case, and in the Indian Ocean to the north-east of the Carlsberg Ridge there is a patch of this deposit in an enclosed basin, where the bottom current must be at a minimum; nor in this connexion do we know anything regarding the mode of formation of the manganese nodules that are so characteristic of Red Clay deposits, and even less regarding the original source of the manganese.

Dr. Schott is to be congratulated on the completion of this most valuable work, in which he has rendered available so much information; but if there is one thing that is brought out most clearly, it is the great need of further investigation in every part of these oceans, which are "by nature left free for all men to deal withal, as very sufficient for all men's use, and large enough for all men's industry". R. B. SEYMOUR SEWELL.

All Manner of Televiewers

(1) Television Reception:
Construction and Operation of a Cathode Ray Tube Receiver for the Reception of Ultra-Short Wave Television Broadcasting. By Manfred von Ardenne. Translated by O. S. Puckle. Pp. xv + 121 + 43 plates. (London: Chapman and Hall, Ltd., 1936.) 10*s.* 6*d.* net.

(2) Popular Television:
Up-to-date Principles and Practice explained in Simple Language. By H. J. Barton Chapple. Pp. xiii + 112. (London: Sir Isaac Pitman and Sons, Ltd., 1935.) 2*s.* 6*d.* net.

(3) Television
By M. G. Scroggie. (Blackie's "Technique" Series.) Pp. ix + 68 + 7 plates. (London and Glasgow: Blackie and Son, Ltd., 1935.) 3*s.* 6*d.* net.

HE is a wise author who knows his own reader; he is a daring author who writes for more than one reader. The first public demonstrations of high-definition television will have rekindled the enthusiasm of the three main classes of potential televiewer, and these enthusiasts will turn to such books as those now before us for some guidance on how television works. On the criteria suggested, Baron von Ardenne is the wisest, Mr. Barton Chapple the most heroic, of our three authors. Mr. Barton Chapple writes for "the public", Mr. Scroggie, in an attractive preface, explains that he has tried to provide "a fairly comprehensive and unpadded survey for [the wireless amateur] without being unintelligibly concentrated for [the non-technical public]; so that neither is the one exasperated nor the other bewildered". Baron von Ardenne, with his more-than-translator and almost co-author Mr. Puckle, address themselves to the advanced amateur and the engineer. Mr. Scroggie's *via media* proves itself *tutissima* and his book can be recommended to the "wireless amateur who is already familiar with ordinary broadcasting"—and the class is an amazingly large one—as a clear well-balanced account of the present state and immediate possibilities of television, with a sufficient glance at the obsolescent, and a fair-minded scrutiny of the up-to-date. Mr. Barton Chapple does not wholly succeed in his difficult task of speaking to the non-technical public without going beyond its limited vocabulary; there are points at which he probably leaves it bewildered by dropping unconsciously back into the familiar jargon of the wireless amateur and engineer. His book is a good one, but he could make it better in its next edition by forgetting the wireless amateur and writing for one intelligent middle-aged lady who would like to know how she is to see the coronation next year from Croydon.

Baron von Ardenne's important work reveals the magnitude of the self-imposed task which will be undertaken by the many advanced amateurs who decide to build their own receivers for high-definition television. He does not gloss over the economic and technical difficulties and he produces, as he always does, a stimulating book which will certainly, as he hopes, "provide an impulse towards intense activity on the part of amateurs in the newest and perhaps most interesting branch of electrical engineering". He is also fully justified in his "hope that certain paragraphs will bring to the television specialist some fundamentally new ideas".

The book is not easy reading, for it is compressed and occasionally elliptic, but it never goes further in these directions than is compatible with stimulation short of exasperation. The keen amateur will have to stop fairly frequently to think how much has been said and how much the author has assumed it safe to leave unsaid because his selected reader will know already. The "construction and operation of a cathode ray tube receiver for the reception of ultra-short wave television broadcasting" will be made possible, but not disappointingly easy, for the advanced amateur who has the good fortune to read this book—and what fun, what fury and despair, what triumphs it will open up for him! The general treatment is philosophically and scientifically excellent, the book contains technical data not readily available elsewhere, and the detailed "Parts Lists", circuit diagrams, and descriptive material on mains supply units, time bases, filters, picture receivers and sound receivers are clear and satisfactory.

It has already been indicated that the book is more than a translation. Mr. Puckle, who has himself done very notable work in the advance of high-definition television, has introduced into the text a considerable amount of matter designed to help the home-constructor who is to deal with the London as opposed to the Berlin television service. These additions are very valuable, indeed essential, but it would have been better to set clearer boundary marks between the von Ardenne and the Puckle contributions. The joints at present are neither perfect welds nor good clean lap joints. The translation is adequately done, there are no defects in clarity, but Baron von Ardenne's colloquially flexible German takes on an occasionally forbidding aspect in the rigidities of a safe translation.

No one with a serious technical interest in television can afford to be without von Ardenne–Puckle; no one who can read Scroggie's lucid and relatively easy survey will fail to find pleasure and benefit in climbing to the more austere heights with von Ardenne and Puckle.

Collected Works of Kepler

Bibliographia Kepleriana: ein Führer durch das gedruckte Schrifttum von Johannes Kepler. Im Auftrag der Bayerischen Akademie der Wissenschaften. Unter Mitarbeit von Ludwig Rothenfelder. Herausgegeben von Max Caspar. Pp. 158 + 86 plates. (München: C. H. Beck'sche Verlagsbuchhandlung, 1936.) 18.50 gold marks.

A POPULAR version of Kepler's letters was published in 1930 by Messrs. Caspar and von Dyck, and was reviewed in NATURE of November 29, 1930, p. 835. Since then Prof. Walther von Dyck has died. We learn that he never lost an opportunity of pressing the claims of Kepler for a collected edition other than that of Frisch—which is open to many objections—and of collecting and studying any documents by Kepler, of which there are a great many. Before he died he had the satisfaction of seeing the Bavarian Academy of Sciences in Munich, with the co-operation of the Deutsche Forschungsgemeinschaft, consent to become responsible for the work. It has named Prof. Max Caspar as editor, and the Würtemberg State Government has set him free from other work for the purpose. He dedicates this volume to Walther von Dyck, and has been able to use the material collected by Dr. Rothenfelder.

The present volume consists of the bibliography preparatory to this edition. The preparatory work seems to have been very thoroughly done. Many of the manuscripts are at Poulkovo. There are certain known collections, public and private. Besides these, circulars were sent out to some 180 libraries, mostly in the neighbourhood of Kepler's residences, to ask them what editions or manuscripts of Kepler they possessed. Most of them replied. It was not to be expected that this step could lead to a large addition to the known works, but some idea of the distribution of these could be got, and also the practical certainty that if any work was missing, it might be looked for elsewhere in vain. However, it *did* lead to certain finds, though not to very important ones.

Actually what we have in this work is, after a preface, eighteen pages of introduction; then four pages of a facsimile of Kepler's communication to Guldin, giving a list of his works edited up to 1621; then sixty-eight pages of works printed in Kepler's time, carefully collated, and each with a descriptive supplement. Several of the minor works have been sought in vain. As Prof. Caspar remarks, "a bibliographer must know what each individual writing contains, from what view it is treated, what is its relation to the whole. So, only a few works receive mention in this book, that I have not been able to see for myself, and for which I had to content myself with taking them out of catalogues, because I could not inspect the originals. All care was taken to give the titles exactly." There are eighty-six titles under this section, originals or duplicates.

After the formal bibliography comes a description of each work. These are pretty full. For example, we note "51. *Calendarium und Prognosticum auf das Jahr* 1617", which Prof. Caspar has not been able to find. In spite of that, there is half a page upon it. These 'prognostics' Kepler did simply to get bread, because the foolish public would buy them. He condemned bitterly the time spent upon them, as being akin to begging, and scarcely in any way more venial—though he does not seem to have altogether disbelieved them.

After that we have seventy-six entries, or twenty pages, of briefer descriptions of various works of Kepler published afterwards, up to the present day. Then, still more briefly, a list of 224 writings which are about Kepler, or which contain some notable reference to him, also continued up to the present day. Then an alphabetical list (3 pp.) of the works in the first section; then a list (3 pp.) of the libraries quoted, and then four pages devoted to the names referred to. Then, a most valuable section, photographic facsimiles, reduced to fit the page, of all except a few of the title pages contained in the first section. Some of these are in two colours. All this has been done as well as possible, and, of course, costs money. The comparatively low charge to the public is because

Prof. von Dyck was able to allocate funds to this purpose which he had received from the Rhineland industry for investigations relating to Kepler.

Prof. Caspar shows a commendable enthusiasm for his subject, but it seems to us he altogether overrates Kepler as a mathematician. Admitted that Kepler was an outstanding man, a genius in his wild way, and that he had a hard life, and that without courage and strong convictions he would never have discovered 'Kepler's laws'; but because he did so, the world has put him into a niche from which he cannot be displaced. Of course, that happened after his death, when I suppose it did not matter to him how the world treated him. It is no part for this journal to decide whether he was or was not greater than his great contemporaries, Galileo and Tycho Brahe, still less, to step across time and compare him with his predecessor Copernicus and the rest, or his successors, Descartes, Huygens and Newton. But, to take an example—*Harmonices Mundi Libri V*, 1619, contains 'Kepler's third law', which is a very valuable asset; but it also contains a lot of sheer nonsense which no one now thinks of, except to dismiss it, such as the music of the spheres, spelt out in the notes each planet makes, with the remark that the earth utters those notes because misery and famine were found there. No doubt they were; so, too, were the courage and tenacity of a Kepler. Also some things with a less personal point and which we are able to judge impartially, such as the relations of the distances of the planets to the sides of the regular solids. We get no notion at all of this from Prof. Caspar's description. To translate a specimen: "The beginnings of this great work reach back to the earliest adult years, its roots are in the deepest soil of Kepler's thinking. He reveals to us the innermost kernel of his views on Nature and the World, he utters the last word of what he knows how to say of the Cosmos and the position of men. We see here not merely the astronomer . . ." and so forth; all rather rhetorical to our thinking. Although the technical work seems to be well done, this exaggerated language is characteristic. R. A. S.

The 'Factor School' in Psychology

Ability and Knowledge:
the Standpoint of the London School. By Frank C. Thomas. Pp. xx+338. (London: Macmillan and Co., Ltd., 1935.) 15*s*. net.

THE number and character of contending schools of psychology were well brought out a few years ago in a large volume issued in America under the title "Psychologies of 1930". No fewer than eleven schools came under review, one of them being the "Factor School", created by Prof. C. Spearman, and described by him as a school to end schools. That the other schools still flourish—for there is no one of them which does not contain some portion of the truth—does not prove that Prof. Spearman's expectation, or at least his hope, is entirely disappointed. On the contrary it is probably true to say that his theory of a general factor (the now rather famous g) and of a variety of specific factors in ability holds the field more securely than ever; and it is equally true to say that his analysis of the birth and growth of knowledge places the psychological study of cognition on a more scientific footing than has ever existed before. After reading Spearman, one can scarcely resist the conclusion that the time has come when William James's lament that psychology was no science, but only the hope of a science, is no longer justifiable.

Prof. Spearman's large books, however, and his extensive series of contributions to learned journals, make heavy going for many people who are not professional psychologists, but who yet desire a statement, which shall be clear without being superficial, of the steps of his argument. Such readers are numerous, and they include, in particular, workers in the fields of education, vocational guidance, and industrial psychology. For them, Mr. F. C. Thomas has written this excellent handbook.

In this book Mr. Thomas really takes up the position of a teacher who, having mastered his subject, takes a keen interest in presenting its essentials with all the lucidity of which its nature admits. We observe that Prof. Spearman and Prof. F. A. P. Aveling, to both of whom Mr. Thomas acknowledges his indebtedness as their former pupil, are abundantly satisfied as to the accuracy of the book as a statement of their joint position. Further, we believe we can answer for it that the readers whom Mr. Thomas has specially in view will be equally satisfied. He modestly disclaims any but "the most ordinary literary facility". We can certify, however, that the book is so well written that not once have we been compelled to re-read a sentence in order to be sure of its meaning.

(1) Bird-Lovers' Manuals

How to Know British Birds. By Norman H. Joy. Pp. 136+40 plates. Birds of the Green Belt and the Country around London. By R. M. Lockley. Pp. xix+236+4 plates. 5*s*. net each.

(2) The Birds of the Firth of Clyde:

including Ayrshire, Renfrewshire, Buteshire, Dumbartonshire and South Argyllshire. By John Morell McWilliam. Pp. 164+10 plates. 12*s*. 6*d*. net.

(London: H. F. and G. Witherby, 1936.)

THE house of Witherby, under the direction of a distinguished ornithologist, is justly renowned for its bird-books, both technical and popular. Two of the works named above belong to a new series of "Bird Lovers' Manuals" which seem likely to have a wide appeal.

(1) Dr. Joy's volume is a handy work of reference, intended primarily as an aid to identification. To this purpose it is admirably suited. Emphasis is laid on distinguishing characters rather than on general descriptions, and the value of song and call-notes in this respect is recognized. The numerous illustrations are well designed for their particular aim, and make the book very good value indeed for its modest price. Mr. Lockley's volume is a guide to bird haunts in the neighbourhood of London. Each chapter deals with a particular type of habitat, ranging from chalk country to salt marsh, from orchard and park to heather and pines, and pleasantly describes its characteristic bird-life. Actual localities are named, even means of getting there being indicated, and the book should prove very helpful to many who wish to explore the home counties in search of birds.

(2) Mr. McWilliam's book fills a gap among the local faunistic studies of its kind. It gives a straightforward and useful account of the occurrence of different species in the Firth of Clyde and the counties bordering it: the area, of course, includes the great sea-bird nursery of Ailsa Craig.

Das Zooplankton der Binnengewässer:

Einführung in die Systematik und Ökologie des tierischen Limnoplanktons mit besonderer Berücksichtigung der Gewässer Mitteleuropas. Von Prof. Dr. W. M. Rylov. (Die Binnengewässer: Einzeldarstellungen aus der Limnologie und ihren Nachbargebieten, herausgegeben von Prof. Dr. August Thienemann. Band 15). Pp. x+272+30 plates. (Stuttgart: E. Schweizerbart'sche Verlagsbuchhandlung (Erwin Nägele) G.m.b.H., 1935.) 30 gold marks.

THIS work should perhaps have been entitled "Introduction to the Study of the Zooplankton". It is essentially a book for the student or one about to embark upon some limnological problem, and in these cases it should prove of the greatest value.

In the general introductory chapter, as well as in the sections dealing with the main groups of planktonic animals, there will be found in outline the present-day knowledge of such problems as reproduction, food, adaptations and vertical and horizontal distribution of the freshwater zooplankton. There is given, too, a brief introduction to the question of seasonal form variation and to the hypotheses of Wesenberg-Lund, Ostwald and Woltereck. References to a full literature list enable any particular aspect to be pursued in greater detail. Finally, the diagnostic keys, descriptions and plates of only those animals most likely to be encountered will greatly facilitate the task of sorting and identifying collections made in the field.

For the more advanced worker the book is naturally of less value, since the greater part is devoted to systematic descriptions of the commoner Rotifera, Cladocera and Copepoda of the plankton. The list of synonyms (pp. 221–224) is of service to those whose interests are only secondarily systematic. From it they will learn, surely with regret, that the genus *Keratella* disguises such characteristic rotifers as *Anurœa cochlearis* and *An. aculeata*, and that the latter now becomes *K. quadrata*.

General Chemistry:

an Elementary Survey; emphasizing Industrial Applications of Fundamental Principles. By Prof. Horace G. Deming. Fourth edition, rewritten and revised. Pp. xiii+774. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1935.) 17*s*. 6*d*. net.

PROF. DEMING'S popular text-book has been extensively revised in its new edition, and many new sections have been added. It now contains brief, but accurate, accounts of numerous modern physicochemical topics, such as photochemistry, the Raman effect, atomic structure and valency (Chapter xxiii), activity theory of electrolytes and *p*H values. The industrial sections have also been revised and amplified to take account of modern practice.

Although the interest and value of the book have been greatly increased, its appeal to the more elementary student is lessened. The reviewer is not altogether in sympathy with the plan of introducing unbalanced equations in the earlier part of the book, as this will encourage a habit which teachers find it hard enough as it is to eradicate among students. Balancing equations should be taught as soon as they are used.

Prof. Deming's book, although it does not fit in with any English course, will be found very interesting and suggestive by teachers.

The Self in Psychology:

a Study in the Foundations of Personality. By A. H. B. Allen. (Psyche Monographs, No. 5.) Pp. 282. (London: Kegan Paul and Co., Ltd., 1935.) 10*s*.6*d*. net.

MR. ALLEN, with whom we are familiar as the author of "Pleasure and Instinct", gives us his views on the relation of the self to psychology. Many of the moderns will find it difficult to accept his definition of psychology as the natural history of the *conscious* experience of *men*. Are the rest of the animal kingdom to be denied any consideration under the caption psychology? That the study of subjective experiences is the sole province of psychology, and that those phenomena which are only open to inspection by another observer are not to be included seems to us an alarming doctrine, to say the least of it.

Indian Conjuring

By Lieut.-Colonel R. H. Elliot, late I.M.S.

THERE is a widespread belief among British people who have not visited the East that India is the 'home of mystery'. I have come across not a few men and women in high and responsible positions who share this erroneous idea. In 'the dim red dawn of man' every strange natural phenomenon was ascribed to the supernatural. Slowly but surely knowledge grew, explanations displaced superstition, and reason, greatly daring, trespassed more and more on the once undisputed domains of the gods, with the result that one mystery after another was resolved by the onward march of common sense. The area of the 'supernormal' has steadily shrunk, and is daily still shrinking. The discovery of facts has always preceded the explanation of their causal origin. There are many things which still puzzle us ; we have no valid explanation for them ; we freely admit our ignorance and wait for the advance of the tide of knowledge which we believe will sweep on irresistible and ever progressive, washing out as it goes the ripples on the sands of ignorance.

In the early days of our colonization of the East, men watched with wonder the fearlessness with which the Indian snake-man handled his dangerous pets. They saw 'the mango trick', the disappearance of the girl from the basket which was stabbed in every direction by a sword, and the speedy return of the young woman unharmed at the bidding of her master. Then there was the duck, which bobbed at every word of command, answering by the number of its bobs the questions of the performer, and so on. At first the European looked on at these and at a number of other wonders of the same kind, and following the line of least resistance, ascribed the phenomena to mysterious causes which were beyond finding out. As time went on, men who had been imbued with an interest in conjuring before they left 'home', started to study the 'tricks' which had obtained so wide a fame. To their surprise they soon found that conjuring as practised in the East was dependent on the very same factors which governed the art they had learnt at home.

The veil of mystery which had shrouded the Orient was little by little lifted to expose trickery, misdirection and humbug. There was, however, one great difference. In the West, the performer made no bones about the fact that he was deceiving his audience, whilst the Eastern always claimed supernatural powers for himself. Around all his doings he threw a veil of mystery ; he was and is a past-master in the art of humbugging his clientele ; he never allowed one of his tricks to be taken as a laughing matter ; his whole technique was that of the 'priest of mystery' ; the matter was a very serious one, no matter how trivial the 'experiment'—he would not have it called a trick for anything—might be.

Step by step our people unravelled the mysteries, dragged them into light and saw them in all their pitiful fraudulence, until it became clear that the fact that a man has a brown, black or yellow skin, and lives in far-away parts of the earth little known to the majority of us, gives him no claim whatever to mystery. Man is man wherever you may find him ; his powers are as limited in China as in Chiswick, in Tibet as in Tooting. Nearly 2000 years ago Tacitus coined the phrase "omne ignotum pro magnifico", a dictum which has pricked the bubble of many a mystery. The wonderful 'mango trick' is based on such barefaced deception that were a performer to present it before the "Magic Circle" at one of our monthly meetings, he would be laughed off the stage. The marvellous nodding duck is dependent on a principle so elementary that my grandson of eleven years of age—a budding magician—would hesitate to use it, unless it were combined with other methods which would help to conceal the fraud. The earthenware medallion, on which the Christian is invited to inscribe the symbol of his faith, with the result that though the disk is ground to powder beneath his foot, the cross is found imprinted on his hand, suffices at first to astonish the subject of the experiment, until he has had time—provided he has the intellect—to solve the very simple device which led him astray. The wonderful seer who reads your fortune in the sand tells you things which seem supernatural in their source, unless you realize that your personal servant has been impanelled to help deceive you. Your conversation has been listened to, your letters read and the information so gained has been handed to the 'holy man' in exchange for the receipt of a small coin of the realm. One might go on with a number of other 'tricks' ; and please note that 'tricks' they are, nothing more and nothing less.

At the present time, most sensible people know all about the majority of these wonders of the East, but two remain to puzzle and disconcert a number of our fellow-countrymen, even including some who have spent the best years of their lives in the East. I refer to the 'Rope Trick' and to 'Levitation'. The Occult Committee of the Magic Circle, a Committee of which I have the honour to be chairman, spent a great deal of time sifting the evidence in favour of the former performance, for which supernatural origin has been so freely claimed. At a meeting held in London on April 30, 1934, with the late Lord Ampthill, a former acting-Viceroy of India, in the chair, we submitted a résumé of the evidence which we had collected. Lord Ampthill said that during his viceroyalty he had tried hard to see the 'rope trick', but in vain. Similar evidence had been sent us by letter from the late Viceroy, Lord Irwin. Lord Meston, the Right Rev. the Bishop Welldon (formerly Metropolitan of India), Sir Michael O'Dwyer and others supported Lord Ampthill, whilst the last-named mentioned that he had asked the Nizam of Hyderabad if he could help him, but though probably the most powerful prince in India, His Highness could not do so. Those who are interested in the subject will find it fully discussed in the second and third chapters of my book "The Myth of the Mystic East" (Blackwood).

No better illustration could be given of the way in which evidence in favour of this trick has been adduced than the statement made by a correspondent in the *Western Morning News* of November 29, 1934, who wrote as follows: "According to a correspondent, the Indian Rope Trick was performed before several hundreds of men who landed in India from Her Majesty's troopship Malabar. It was performed several times a day, not in bad light or when it was dark, but in the full light of the Indian sun. The Duke of Connaught watched the performance sitting on his horse and seemed highly interested." This story, so circumstantially told, seemed as if it must be true, but I had the privilege of being able to submit it to His Royal Highness, through the kindness of a member of his staff, and this is the reply I received: "With reference to the enclosed letter from Colonel Elliot, I sent it to the Duke. Quoting from his letter, he says: 'After these many years I am unable to remember small events of that time, but I have no recollection of ever having seen the rope trick during my service in India, or even heard of it.'" It is impossible to believe that His Royal Highness would ever have forgotten such a supernormal happening. I am greatly in His Royal Highness's debt for so graciously answering my question. It serves to show the way in which the names of our Royal Family are used behind their backs, in a manner which it is very difficult for them to resent. Their outstanding popularity carries great weight with the public, and leads many people to accept stories as ridiculous as this.

There are two recent incidents which deserve a brief mention. The first of these was the so-called 'Cheltenham Rope Trick'. A gentleman who styled himself "Professor" declared that he had discovered how to perform the 'Indian Rope Trick', and had actually done it before a meeting of a society of conjurers. This statement was widely advertised in the Press, and a local photographer stated that he had photographed a girl "as she reached the top of the rope—but when he developed the film, to his amazement, no trace of the girl was to be seen. The rope was bare". I took some trouble to run this story to earth, and was in communication with officials of the society, and with a gentleman of undoubted honesty who was present at the meeting in question. What did it all amount to ? It was just a joke at the expense of the local press-man. A wire had been suspended between the tops of two tall trees, a rope was hung from this, care being taken so to arrange the light that the wire was not visible, and the dupe was told that just before his arrival a girl had ascended the rope and disappeared. The members of the society were much annoyed at the publicity that this trick had attracted and were very unwilling that more publicity should be given to it than they could help. I had to fall in with their wishes. Measures had been taken to prevent any further absurd claims being made. All the same, from time to time notices appeared in the Press, dealing with this incident as if it were worthy of credence instead of being the joke—perhaps not in the best of taste—that it was. My son sent me a copy of it from an Indian paper in which it was taken seriously.

There remains the 'Plymouth Demonstration of the Rope Trick' by Karachi, who, by the way, in private life was a Mr. Arthur Darby. There can be no doubt that a number of honest witnesses, who, however, had not had the benefit of a training in conjuring, were taken in by Karachi, who was simply performing a conjuring trick, which some people have thought very clever, but which to those of us who have studied conjuring was a very cheap form of deception. Mr. Harry Price exposed it in the *Listener* (January 16, 1935), and there was a lot of correspondence on the subject, much of which called to mind Carlyle's bitter dictum on the subject of the intelligence of the population of Great Britain.

The other much disputed topic is that of the power of Oriental fakirs to practise 'levitation'. Many years ago, Messrs. Maskelyne put on a show in which a girl was apparently suspended in mid-air lying horizontally. Hoops were passed round her in various directions to show that there were no mechanical aids to her flotation. It need scarcely be said that it was simply a clever piece of illusion. The Eastern magician presents a similar trick, and much has been made of it in a recent issue of the *Illustrated London News*. Many Europeans have seen this clever performance, but some at least of those who have described it have not been very skilled observers. What actually occurs is substantially as follows: The girl lies on the ground and is covered up; a sort of tent is built round her; then under cover of it she is raised up; the tent is gradually taken away bit by bit, until she is seen lying suspended as it were above the ground, but with some of her coverings dropping down to the ground near her head end in what appears a very innocent way. The spectator is not allowed to go up and examine this drapery or he would find out that it conceals an iron post driven into the ground. Were he allowed further license, he would soon discover the secret of the trick, which indeed is very similar to the device used by Maskelyne long ago. An Indian civilian who occupied a high position in the country recently wrote to me describing how he had this trick performed in his compound at a garden-party. Among his guests was a well-known bishop who was greatly troubled by what he took for a satanic manifestation, until the Commissioner asked him how the man described his performance. "As a trick," replied the bishop. "Well, if he only claimed for it that it was a trick you may be sure it was nothing more. He would certainly not err on the side of modesty in his claims."

In reading of, or in listening to descriptions of this trick as given by men who have not had a training in conjuring—the art of suggestion and misdirection—I would urge readers to be very sceptical. They are often misled to think that events happened far differently from what they actually did. Time after time I have heard people describe what they thought they saw, and knowing how the trick was done I have been astonished that they can have been so hopelessly misled as to the real facts. The success of any and every conjuring show depends on this factor of deception.

We read and hear wonderful descriptions of *yogis* buried alive and being none the worse for it. In those cases in which expert conjurers have witnessed such experiments, it has been quite clear that the actual conditions were not those claimed by the performer. By means well known to expert magicians—I use the term without prejudice—the suffocation of the subject was easily avoided, though doubtless the experience was sufficiently unpleasant. I know the wonderful claims that have been put forward, but I have so often had the opportunity of checking such claims by careful observation and discovering their worthlessness that I am very far from being convinced.

Once again I would urge readers to look always for a natural explanation of any phenomenon, and when one is not forthcoming, to await the advent of more knowledge, confident that a normal and not a supernormal explanation is always forthcoming, provided that we have the requisite knowledge.

American Early Tertiary Mammals

THE White River formation of western North America contains numerous well-preserved fossil skeletons of mammals which date back to Oligocene times when some present-day families were beginning to flourish. The rocks seem to have been formed by floods on a very extensive plain, where the carcases of animals which lived under varied conditions were washed together repeatedly during a long period. The fossils therefore give a very good idea of the mammals which were living on the North American continent during a particularly interesting episode in the evolution of mammalian life. They have already been described in numerous scattered works and papers, but modern methods of collecting have provided so many more satisfactory specimens that there is now an opportunity for a comprehensive review of the whole fauna.

Such a review is being undertaken by Prof. W. B. Scott and Prof. G. L. Jepsen, of Princeton University, who have just published the first part of their work dealing with the Insectivora and Carnivora*. None of the Insectivora has the vacuities in the bony palate and the incompleteness of the zygomatic arches which characterize some existing Insectivora, so that these must be regarded as degenerate, not primitive features. Of the Creodonta or earliest Carnivora, only some Hyænodontidæ survive in the American Oligocene, but very fine skeletons have been obtained from the White River formation. The authors are as much puzzled as previous investigators to explain the use of the long passage above the palate of

---

* The Mammalian Fauna of the White River Oligocene. Part I. Insectivora and Carnivora. *Trans. Amer. Phil. Soc.*, N.S., 28, Part 1. Pp. ii+153+22 pl. (Philadelphia: American Philosophical Society; London: Oxford University Press, 1936.)

Hyænodon by which the internal nostrils are displaced as far backwards as those of a crocodile. They remark that "there is no other feature in the teeth or skeleton of the hyænodonts to suggest amphibious habits". They also point out that *Hyænodon* cannot have fed on ants like the existing ant bear (*Myrmecophaga*), which exhibits a nearly similar arrangement of the palate.

The beautifully preserved skeletons of Canidæ or dogs are especially interesting, because they show that in Oligocene times the family was not so completely distinguished from other Carnivora as it is at present, while one genus, *Daphœnus*, seems to be the common ancestor of at least three distinct groups of modern Canidæ. The smaller Oligocene dogs must have looked much like civets.

There are very few Mustelidæ in the White River formation. This family seems to have been much more characteristic of the Old World than of the New World during Oligocene times. Of the Felidæ, no true cats have been found in North America before the Pliocene, but the sabre-tooth cats or Machairodontinæ are well represented in the White River formation. They are all much smaller than the familiar 'sabre-toothed tiger' of later date, but it is interesting to observe that the articulation of the lower jaw in the Oligocene genera is as completely adapted for the wide opening of the mouth as it is in the latest Pleistocene genera. There is no doubt that the sabre-shaped canines were used for stabbing; and one skull of *Nimravus* in the museum of the Dakota State School of Mines exhibits a large gash in the brain-case that was evidently made by such a stab.

From this brief summary it is clear that Prof. Scott and Prof. Jepsen are doing much more than providing technical descriptions of the fossils. They are publishing an illuminating treatise on Oligocene mammals, of which the succeeding parts will be eagerly awaited. A. S. W.

Daniel Gabriel Fahrenheit (1686-1736)

AMONG the many improvers of the thermometer in the eighteenth century, none laboured more assiduously or successfully than Daniel Gabriel Fahrenheit, the German natural philosopher and instrument maker who died in Holland at the early age of fifty years on September 16, 1736. His work was done at a time when the physical and medical sciences were making rapid advances, and there was great need for thermometers of good construction and furnished with a standard scale which could be used for comparisons. It was this need that Fahrenheit met. He was not the first to make thermometers, the first to use alcohol or mercury, or to devise scales with fixed points, but his improvements were such as to make his thermometers known all the world over, and though to-day it is generally recognized that the universal use of the centigrade scale would be a great advantage, the Fahrenheit thermometer seems likely to remain in use for many years yet.

For nearly a century before Fahrenheit's time, men of science had been using thermoscopes and thermometers, and a grand array of names is associated with their early history. Galileo, Boyle, Huygens, Hooke, Halley and others all contributed to the progress of thermometry. Doctors were especially interested in thermometers by which the temperature of human beings and animals could be taken, while natural philosophers required thermometers as much as barometers. The term 'thermometer' is first mentioned by the French Jesuit, Father Leurechon (1591–1670), in his "Récréation mathematique" published in 1624. The early instruments were subject to changes in atmospheric pressure and were really 'barothermoscopes'. Ferdinand II, Grand Duke of Tuscany (1610–70), founder of the Accademia del Cimento at Florence, was the first to produce a thermometer unaffected by atmospheric pressure.

There were all sorts of ideas regarding the graduation of thermometers. In 1665 Boyle suggested the freezing point of aniseed oil, and Huygens in the same year suggested as fixed points the freezing point and boiling point of water. Snow in very cold weather, the greatest heat in summer and melting butter were also proposed for definite temperatures. There were also many suggestions regarding scales, about a score of scales being used in the eighteenth century, of which, however, those due to Fahrenheit, Réaumur and Celsuis, or perhaps more correctly Martin Strömer, alone survived.

It is well known that Fahrenheit was the first to bring the mercurial thermometer into general use, that he devised his well-known scale about 1714, and that he described his method of making thermometers in five short papers in Latin to the Royal Society in 1724, but it is not generally known how he came to be an instrument maker. The bicentenary of his death, however, has led to the publication of a biographical memoir in the *Transactions of the Royal Academy of Sciences of*

Amsterdam, the authors of which, E. Cohen and W. A. T. Cohen-de Meester, add a great deal to our knowledge of Fahrenheit's personal history. This memoir shows Fahrenheit in a most pleasing light, gleaning information from many sources, writing and lecturing on such things as hydrostatics, optics and chemistry, and consorting with some of the most learned men of his time. Of special interest in this memoir are the references to some letters not long ago discovered in Leningrad. In one of these, written on April 17, 1729, to the famous physician Boerhaave, Fahrenheit tells of a visit in 1708 to the Danish astronomer Römer, whom he found placing thermometers in a mixture of ice and water and in blood-warm water. Inspired by his contact with Römer, Fahrenheit began to read about barometers and thermometers and studied the memoirs of Maraldi, de La Hire and Amontons in the publications of the Paris Academy of Sciences. Of the writings of British physicists, he knew only of Boyle's works, so far as they had been translated into Latin, as it was not until his visit to England and his election into the Royal Society in 1724 that he studied English.

Born in Dantzig on May 24, 1686, Fahrenheit was the eldest of a family of three boys and two girls, who were left orphans in August 1701 by the accidental death of both father and mother. He was sent by his guardian to Amsterdam to a merchant's house to learn business, and as a young man made journeys into Denmark, Sweden, Germany and Russia, probably settling finally in 1715 in Amsterdam, where by his lectures he stimulated the study of physical science and where he constructed the thermometers for which he will always be remembered. In 1736 he secured a patent for a mill for draining purposes but did not live to reap any benefit therefrom. His death took place at The Hague, and four days later he was buried in the Kloster kirke, the register of which contains the entry "Am 20 September 1736 am Tage begraben in dem Gewölbe unter dem Chor Daniel Gabriel Fahrenheit. Für Miete des Grabes und zwei Läuten 18 Gulden".

The memoir on Fahrenheit to which reference has been made above contains portraits of several of his most celebrated contemporaries, including Boerhaave, Römer, s'Gravesande, Musschenbroek and Nieuwentyt, but none of Fahrenheit himself.

Obituary

Mr. William Rintoul, O.B.E.

MR. WILLIAM RINTOUL died at the age of sixty-six years at his home in Ardrossan, Ayrshire, on August 25, after nearly a year's illness. His career had been a remarkable one, and began in Glasgow, where he was educated and received in Anderson's College his scientific training. In the late 'eighties there were (as there are even now) few schools of analytical chemistry. so that Mr. R. R. Tatlock not only filled the post of city analyst but also himself lectured and had a staff of lecturers on chemistry and physics to students many of whom afterwards became his assistants and later occupied important positions in the chemical profession. Ramsay was one of them.

After a short time as an assistant, Rintoul lectured to Tatlock's students until in 1891 a post of chemist offered in a paint manufacturer's near London, where he got chemical and works experience. After three years there he went in 1894 to the Royal Gunpowder Factory as a chemist in the laboratory, later becoming chemist-in-charge of the manufacture of nitroglycerine, and for two years before he resigned he was chief chemist in the laboratory.

At this time the Royal Gunpowder Factory under Sir Frederic Nathan as superintendent and Mr. James Thomson as manager led the explosives industry in Great Britain in organization, in safety precautions and in the invention of new processes and plant. Rintoul, naturally inventive and of remarkable manual skill, did his full share, of which the displacement process for the manufacture of nitroglycerine is an example. This process improved the manufacture of that explosive economically in that no high buildings were required to house the plant and also from the point of view of safety, as the nitroglycerine was removed (by upward displacement) from its acid mixture as soon as it had been formed and was sent at once for its preliminary washing, instead of being left to separate in bulk in an acid, and more or less dangerous, state. At this time also he was co-inventor with Robertson of a process and plant for the recovery of acetone, the solvent used in the manufacture of cordite.

Accompanying Sir Frederic Nathan to Nobel's Explosives Company (now part of Imperial Chemical Industries, Ltd.) at Ardeer in Ayrshire in 1909 as chief chemist, he became research manager there and devoted himself to the organization of the laboratories and erection of many new ones. His policy had several features which have been commended by others in like position, as for example, the provision that all chemists, whether destined for research or plant, should first undergo a thorough training in analytical chemical methods, the insistence on a good system of documentation of reports and of published work, the installation of physical methods of testing explosives and close contact with the universities.

While at Ardeer he was associated with a number of patents chiefly on stabilizers for explosives, and developed a keen interest in biochemical investigations, some of which are described (with Raistrick) in the *Philosophical Transactions of the Royal Society*.

About ten years ago Rintoul was brought up to the headquarters of Imperial Chemical Industries, Ltd., as a director of its research organization, from which he maintained an active and sympathetic contact with all the company's laboratories, and came into close touch with many prominent scientific men who were working directly or indirectly in the company's interests, for it was part of his duty to administer the support given by the company to widespread scientific activities. In these matters he gained the respect and affection of everyone with whom he came in contact, and as representative of his firm was well known abroad, where he attended many conferences.

Rintoul was made an O.B.E. for his work in the Great War, and assisted on many committees such as the Councils of the Chemical Society and Institute of Chemistry, the Safety in Mines Research Board, the Chemistry Research Board (D.S.I.R.), the Research Committee of the Midland Railway and the British Standards Institution. When he died he was president of the Faraday Society, in the discussions of which he took much interest.

Rintoul married twice: first Lottie Edwards, by whom he had two sons and a daughter, and secondly, two years ago, Jess Isabel Robertson.

R. ROBERTSON.

Dr. N. A. F. Moos

To those interested in terrestrial magnetism and in Indian science, the name of Dr. Nanabhai Ardesher Framji Moos is well known, and they will learn with regret from *Current Science* for June of his death on March 12 last. Born in 1859, he graduated in engineering at the Poona College of Science in 1878, and after some years of teaching there entered the University of Edinburgh, taking the B.Sc. degree with distinction in 1886. On his return to India he held a series of appointments, including that of professor of physics at the Elphinstone College, Bombay.

At that time the observatory at Colaba, Bombay, was in charge of Mr. C. Chambers; and on his death, in 1896, Moos was appointed director, soon having the responsibility of overcoming the disturbances produced in the magnetic records by electric traction in the city. He shifted the magnetic work to a new observatory at Alibag, where he was most successful in handling the architectural difficulties of a constant-temperature room.

Moos had all the faithful conscientiousness that is found in Indian officers, and to that he added much of the Parsee energy and enterprise. His training in engineering, as well as in physics, gave him considerable interest in instrumental design, so that he loved to work out new patterns in seismometers. But his outstanding feature was his devotion to the observatory. He was ever on the look-out for new apparatus, and was determined that, if he could bring it about, the equipment of Bombay should not be inferior to that of any observatory in the world. For the financial difficulties of those in administrative charge, his sympathy was, not unnaturally, somewhat restricted; but in spite of an occasional disappointment his loyalty to his work never flagged.

Moos's great opportunity came with the plan for putting together and discussing the complete series of observations of the old Bombay Observatory; and the two volumes of "Colaba Magnetic Data, 1846–1905" are a monument of conscientious and successful labour. They form an indispensable part of the equipment of a magnetic library.

Moos had always taken a keen interest in the university life of Bombay, and after his official retirement in 1919 his active participation was kept up until the end.

G. T. W.

Mr. J. L. Hodgson

MR. JOHN L. HODGSON died on August 14 at his home near Leighton Buzzard, at the early age of fifty-five years. Born at Lincoln and receiving his technical training at Nottingham University College, he leaves a life record of very valuable work in the engineering world. On the practical side, he served with Messrs. William Walker, the Gedling Colliery, Yarrow and Co., where he was associated with the late Sir Alfred Yarrow in research work on speed ships and destroyer design. About 1910 he was appointed to the staff of George Kent Ltd., of London, and became the technical adviser on all matters connected with the metering and control of air, gas and steam. It was he who designed the first Venturi air meters, which were installed by the Victoria Falls Power Co. He was also intimately concerned with the ventilation arrangements of the Mersey Tunnel. For one of his papers dealing with the use of the orifice for the measurement of fluid he was awarded the Telford Medal by the Institution of Civil Engineers.

Throughout his life, Hodgson abhorred waste in all forms, believing that scientific discovery and invention should be used for the service of man, and not for his destruction. He was one of the founders of the Engineers' Study Group, which was formed to study how and why there is "poverty amidst plenty" in our age. His death will be a severe loss to many friends.

WE regret to announce the following deaths:

Dr. Alexander Anderson, formerly president of University College, Galway, on September 5, aged seventy-eight years.

Mr. E. R. Deacon, O.B.E., head of the high explosives branch of the Directorate of Explosives Research, Woolwich, on August 29, aged fifty-four years.

Lord Moynihan, emeritus professor of surgery in the University of Leeds, and president in 1926–32 of the Royal College of Surgeons of England, on September 7, aged seventy years.

News and Views

The British Association and Social Science

THE Report of the Council of the British Association, adopted by the General Committee on September 9 at Blackpool, included two matters of particular interest relating to the development of the activities of the Association in the field of the social sciences. During the year covered by the Report, the Council appointed a Committee to consider how the Association might indicate the importance which it attaches to the development of the social sciences, either by the appointment of a third general secretary or by other appropriate means. As a result, this year's programme includes in a separate section the titles of addresses, papers, and discussions having a special bearing upon the relations between science and the interests of the community. Communications appropriate to this group may be suggested by organizing sectional committees or by sectional presidents. At least one discussion in each annual programme is to deal with the application of science to social problems, and at least one of the evening discourses. By these developments, it is intended to provide the evidence which public opinion now demands that the Association shall carry out one of its original aims, namely, that of "obtaining a more general interest for the objects of science".

Incorporation of the British Science Guild

IN the same spirit, the General Committee accepted the recommendation of the Council for the incorporation of the British Science Guild in the Association. It will be remembered that the Guild was the outcome of Sir Norman Lockyer's presidential address to the Association, at the Southport meeting thirty-three years ago, on "Influence of Brain Power on History". The stated object of the Guild is "to promote the application of scientific method and results to social problems and public affairs". As is pointed out in the Report adopted at Blackpool, the same object is implicit in the aims of the Association; and the programmes of recent meetings have given evidence of a greater concern for these problems than was commonly exhibited in former years. The terms of the incorporation of the Guild in the Association include the transfer of the capital funds of the Guild to the Association, together with contingent bequests from Lady Lockyer and Sir Albert Howard. The Council of the Association will appoint a committee, to be called the British Science Guild Committee, which will be entrusted with arrangements for lectures already initiated by the Guild and for any similar lectures approved by the Council. The Norman Lockyer Lecture is to continue to be delivered annually and to have particular reference to the relations between science and the welfare of the community; and the Alexander Pedler Lecture is to be offered annually to one of the corresponding societies of the Association, or be delivered at a centre outside London. The amalgamation of the two bodies was greatly to be desired, and we are glad that it has now been accomplished. Though, when the Guild was founded, few men of science took active interest in the application of scientific methods to the investigation of social problems, there is now a decided change of attitude in this respect and the columns of NATURE have afforded abundant evidence of such repercussions. The Association has responded to this extended influence, and has thus shown itself to possess the progressive spirit which should be characteristic of every scientific institution.

Jean-Sylvain Bailly (1736-93)

THE bicentenary of the birth of the French astronomer Jean-Sylvain Bailly, who was born in Paris on September 15, 1736, and perished on the scaffold at the age of fifty-seven years, recalls a career of great interest, for Bailly was not only a cultivated and distinguished man of science, but he was also one of the enthusiastic philanthropists who at the coming of the French Revolution adopted with ardour the popular cause and endeavoured to secure for the people sound constitutional reforms. The son of a keeper of the King's pictures, it was intended that he should follow in his father's footsteps as a painter, but literature proved more attractive than art, and science more alluring than either. It was his acquaintance with Lacaille that led him to astronomy, and one of his earliest labours was the reduction of Lacaille's observations on zodiacal stars. He also became known for his researches on Jupiter's satellites, but his greatest work was his "Histoire de l'Astronomie", a work full of animated description, luminous narrative and interesting detail. The correspondent of Voltaire and Buffon, the contemporary of D'Alembert and Diderot, Bailly's versatility was recognized by the unusual honour of his being elected a member of the Academy of Sciences, the French Academy and the Académie des Inscriptions et Belles Lettres.

ALL accounts of Bailly describe him as a man of the highest integrity, generous, courageous and liberal-minded. The popularity he enjoyed led to his election in 1789 as a deputy to the Tiers-Etat and to his being chosen president of the National Assembly. In his capacity of president he dictated to the members the oath taken in the Tennis Court at Versailles on June 20, 1789, "to resist tyrants and tyranny, and never to separate till they had obtained a free constitution". About a month after this, the Bastille fell, and on July 17, when Lafayette was made commander-in-chief of the new National Guard, Bailly was made Mayor of Paris. For two fateful years Bailly held his difficult posts, endeavouring amidst the rising tide of republicanism to serve both King and country. Then came his fall. On July 17, 1791, the demonstration took place in the Champ-des-Mars to secure signatures for a petition demanding the dethronement of the King. There was disorder and violence, Bailly gave the order for the crowd to be dispersed by force, fire was opened, some forty people killed and with the "massacre of the Champ-des-Mars" Bailly's popularity waned. A few months later, he resigned his posts and retired to Nantes. Two more years passed and against advice he visited Laplace at Melun. He was recognized and denounced, and was sent to Paris, where he was tried on November 10, 1793; on the next day he was condemned, and on November 12—a bitterly cold wet day—was taken in an open cart to the ill-fated Champ-des-Mars and there guillotined amidst the execrations of the people he had done his best to serve. Save for Lavoisier, who fell on the scaffold six months later, Bailly was the most distinguished man of science who fell a victim to the Revolution. He had, however, played a conspicuous and honourable part, and to-day his statue stands in the gardens of the Luxembourg.

Vitamin B_1

THE structure of vitamin B_1 was made certain by its synthesis, recently announced from the laboratory of Prof. Williams of Columbia University (see NATURE, Aug. 29, p. 372), and this has now been repeated elsewhere. Grewe (*Hoppe-Seyler's Zeitschrift für physiologische Chemie*, 242, 89; 1936), working in Windaus's laboratory at Gottingen, describes the preparation of the pyrimidine half of the molecule, and completely confirms the latest formula put forward by Williams, though mention is only made of Williams's earlier suggestions which he himself has now modified. Grewe goes on to state that he had intended to work out a synthesis of the vitamin from the new pyrimidine derivative when he learned, through Prof. Windaus, that Andersag and Westphal had already accomplished this in the scientific laboratories of the I.G. at Elberfeld, and that patent protection had been sought. Prof. Williams's work was carried out with the collaboration of Merck and Co., Inc., Rahway, N.J.; it seems, therefore, on the cards that there may be some interesting developments in the patent field, should the synthesis of vitamin B_1 become practicable on a commercial scale.

Half-Castes and World Peace

A NOVEL view of the problem of the half-caste and of the role which might be played by communities of mixed origin in the promotion of world peace is taken by Mr. Cedric Dover in a memorandum which he presented to the International Peace Congress held on September 3–6. In a cursory survey of the figures, he points out that not only are half-castes more numerous than is realized generally, but that they form an appreciable proportion of the populations of the modern world. Mr. Dover, however, does not rely on the mere weight of number. He goes on to argue that half-caste communities, consisting of 'marginal' men, who represent two cultures, and exist under conditions of 'imperialism', owing to the presence of a dominant white population, present parallelisms, due to a common ethnic element derived from their white blood, a common language (English), a common religious belief, and common social and economic conditions. It is suggested, therefore, that the continued growth of ethnic relations and mixed populations should be accepted as part of the machinery of human evolution, of which advantage should be taken to promote the greater ethnic unity and cultural uniformity, which would afford an efficient counter to an aggressive spirit of nationalism, while the creation of a united front of marginal communities would lead inevitably to better international understanding.

IF Mr. Dover's suggestions to this end tend to a more rational attitude towards the half-caste, they will have accomplished much. Miscegenation, however, has not been overlooked as a possible ultimate solution of the colour question; but the world, it would seem, is not yet prepared, on present evidence of the effects of the crossing of widely diverse strains, to foster it deliberately or even to countenance it. The organization of a world-wide front of sufficient strength to make its weight felt demands resources and machinery, of which at present there seems little expectation. Quite possibly local loyalties would prove obstacles stronger than the communal parallelism upon which Mr. Dover would rely.

Roman Leicester

A FURTHER stage in the proceedings which will determine the future of Roman Leicester (see NATURE of August 29, p. 356) was reached on September 3, when an inquiry was held in the city by the Ministry of Health to examine the application of the Leicester Corporation to borrow £135,000 for the purpose of erecting baths on the site adjacent to the Jewry Wall, upon which archæological investigations are being conducted by Miss Kathleen Kenyon. The application was opposed by the Leicester Archæological Society, the Leicester Literary and Philosophical Society and the Leicester Civic Society, bodies co-operating in the excavation. They were represented by Mr. Macgregor Clarkson; and Mr. P. K. Baillie Reynolds, Inspector of Ancient Monuments, was also present, representing the Office of Works. In the course of his evidence, Mr. Clarkson stressed the unique position which the site conferred on Leicester. The recent discoveries, he urged, made it possible to point to the civic centre of the city in three historic periods—the Town Hall of Roman times, the Guildhall of the Middle Ages, and the modern Town Hall. Miss Kenyon's evidence dealt with the important archæological features of the site added by her investigations, including part of the Forum and the ten feet depth added to the Jewry Wall, part of the Roman Town Hall, which, now standing at 35 ft. in total height, is one of the largest Roman walls in Britain. This wall is scheduled as an ancient monument.

THE suggestion put forward by Mr. McEvoy, the Town Clerk, in stating the case for the application, was that excavation should proceed under skilled archæological supervision, the cost entailed over and above the normal cost of excavation to be borne by a local committee representing those interested in ancient remains. Against this, Mr. Colin D. R. Elles, the chairman of the excavation committee, handed in a petition, which had been signed by 3,235 persons in four days only, asking that the remains should be preserved; while Mr. Baillie Reynolds not only stated that his department would look with great favour on any scheme to preserve the remains, but also intimated that the Office of Works would co-operate in laying them out to advantage.

Forensic Medicine

THE Advisory Committee on the Scientific Investigation of Crime, under the chairmanship of Lord Trenchard, recently issued its report (London : H.M. Stationery Office, 1936. *2d.* net), from which it would appear that the teaching of forensic medicine in London is in an extremely backward condition as compared with the teaching of that subject in most of the capitals of Europe, and well behind the standard set in Scotland. As the Committee points out, this is not confined to the restricted sphere of criminal investigation and police practice, but extends to the study of many problems connected with social medicine and to the whole question of medico-legal practice. The Committee recommends the establishment of a medico-legal institute which would act as a training centre for medico-legal experts and as a centre for special pathological research, and it also suggests that facilities should be given for courses of instruction for students of law, coroners and other persons who are associated with medico-legal work.

As to the question of police laboratories, though in certain circumstances it is no doubt advisable to have laboratory facilities under the direction of the police, the proper place for extensive medico-legal investigations is in connexion with departments of universities. If the investigating authorities are to have the facility of obtaining advice on all kinds of scientific subjects, as they must, there is no possibility of so doing if they are restricted to police laboratories. Such advice and assistance can be obtained only through the universities. It is, however, impossible for the police authorities to know what departments to consult, and therefore a department of forensic medicine within the university offers the only means by which full use of the latest advances in science may be obtained. On considering the whole matter, it would appear to be advisable for the authorities in London to concentrate their efforts in founding a Department of Forensic Medicine in connexion with the University of London, and to make the necessary arrangements for the ample material, which is at present largely wasted, to be utilized in the teaching of elementary forensic medicine to medical students and to offer facilities for post-graduate study and research to those who desire to specialize in this subject.

Technical College Equipment

WE have received from an Advisory Committee on Technical College Equipment, British Industries House, Marble Arch, London, W.1, a memorandum on a scheme in progress for setting up an exhibition at British Industries House showing the equipment necessary for technical institutions. This movement is designed to help those responsible for expenditure on these centres in view of the very large outlay anticipated during the next few years by the Board of Education. The Committee represents the three associations concerned with technical teaching and also the Institution of Production Engineers, and hence is an authoritative body. It is pointed out that the present method of deciding on a design, that of visiting recent buildings and utilizing the composite information obtained, wastes time and is unsatisfactory. Technical education in Great Britain is lamentably behind that on the Continent in the matter of material equipment and buildings, hence this scheme is to be commended. The relationships of the pieces of mechanism will no doubt be an important part of the Committee's work, though this must be to some extent subservient to the configuration of the floor space. More difficult will be the presentation of the structural features and service supplies essential as the basis of the equipment. It is stated that the object is to enable full information to be obtained for getting out estimates for building, extending, and equipping institutions. So far as the two former functions are concerned, it seems difficult to see how the exhibition can supply any detailed information, from the province of trained professional advisers and necessarily varying with local conditions; such advisers, however, should be able to learn much from the exhibition.

Geological Survey and Museum: New Activities

A NEW publications stall, where the public may purchase the official guides and geological memoirs, including the series of handbooks on British Regional Geology referred to in NATURE of September 5 (p. 389), has been opened in the entrance hall of the new Geological Museum at South Kensington. The Museum has also published an extensive series of excellent photographic postcards, price *1d.* each, which are likely to be of value to teachers of geology and physical geography. The postcards include reproductions of general views of the Museum, with dioramas and other interesting exhibits; and photographs of British localities of geological interest, with explanatory text, illustrating marine erosion and sea coasts, rock-weathering and denudation, vulcanism, glaciation, and similar subjects. A list is obtainable from the Museum. An experimental series of free public lantern lectures and lecture tours on the geology and scenery of various regions of Great Britain was given last month. The lectures were well attended, and will be continued throughout the winter. Facilities for special parties can be arranged. Recent additions to the exhibited collections include a series of specimens from H.M. Office of Works, illustrating the weathering of the building stone

(Anston stone) of the Houses of Parliament; and a suite of ores illustrating the occurrence of copper at Kilembe, presented by the Geological Survey of Uganda. This occurrence, which is in granulitic rocks, is remarkable for the presence of the cobalt ore linnæite, although arsenic and antimony are absent. Among the donations recently received by the petrographical department there is a valuable series of rock-specimens from the Pre-Cambrian of the Adirondacks, New York State, collected and presented by Dr. A. F. Buddington of Princeton University; and a second fine collection from the Charnwood Forest and Nuneaton areas, presented by Mr. H. H. Gregory of the Leicester Museum.

Empire Fauna at Home and Abroad

THE August number of the *Journal of the Society for the Preservation of the Fauna of the Empire* presents some interesting contrasts in its varied accounts of wild life in different British territories. Capt. C. R. S. Pitman, to whose reports as Game Warden of the Uganda Protectorate NATURE has referred on previous occasions, in a lecture to the Society, explained why organized control of the 21,000 elephants of the Protectorate became necessary. The devastation caused by such great numbers in a limited area (of some 80,000 square miles), where the native population averages forty to the square mile, became intolerable, and yet under organized control, and in spite of the fact that 17,000 elephants have been slain in twelve years, the estimated number remains as it was in 1924. Capt. Pitman is of opinion that organized control is the finest insurance for the adequate perpetuation of the African elephant. From wild Africa we turn to the home of animal protection—and read Miss Frances Pitt's article upon the polecat and pine-marten in Great Britain. The elephants are over-numerous, do serious harm, are deliberately slaughtered, and yet their continued existence is secured; the polecat and pine-marten are rare, are two of the most interesting members of the primitive fauna which survive in Britain, they do no particular harm in any serious degree, and yet—the first is extinct in Scotland and England, and survives only on the Welsh border, and the latter is apparently extinct, or all but extinct, throughout the whole country except in the north-west of Scotland; and almost all because these creatures are liable to find their way into traps set for vermin. It is ironical that while we concern ourselves with the fauna of the Empire abroad, these two creatures should be disappearing in *our* own land under our eyes. Can no step be taken to ensure their adequate perpetuation, as the adequate perpetuation of destructive elephants in Uganda is ensured ?

Marine Biology at Cullercoats

THE Report for the year ending July 31, 1935, of Armstrong College Dove Marine Laboratory, Cullercoats, Northumberland, drawn up by the director, Prof. A. D. Hobson, and published by the Marine Laboratory Committee of Armstrong College, shows a successful period in the history of the Laboratory. Further alterations in the building have given more working space and the library has been extended, with most satisfactory results. Herring observations have been continued in accordance with those of previous years, also salmon investigations, the results of the latter work having been published in the Annual Report of the Tyne Salmon Conservancy Board. Interesting results have been obtained by Dr. Bull in his experiments on conditioned responses in fishes in connexion with changes of salinity, and he has also continued his observations on pollution in the Tyne estuary. Faunistic work, which has been made a speciality of the Laboratory researches, is progressing rapidly, many new additions have been made to the fauna, and a reference collection is in process of formation which will be of great value to future workers. A mussel survey of the Northumberland beds has been completed, and a report prepared and submitted to the Northumberland Sea Fisheries Committee. This report appears in the present publication, showing that the Holy Island and Budle Bay beds are the only areas of importance for bait supplies. Papers on the herring investigations by B. Storrow and Dorothy Cowan, on conditioned responses in fishes (Part 6) by H. O. Bull, and on heterogonic growth in the abdomen of *Carcinus mænas* by J. H. Day (see NATURE, April 18, 1936, p. 669) are also included.

Weed Problems in Australia

As in some other parts of the world, noxious weeds are proving a serious source of trouble in Australia. The problem has been under the consideration of the Standing Committee of Agriculture and independently by several of the bodies represented on it. An arrangement was made in 1934 that as a preliminary to further work an officer of the Council for Scientific and Industrial Research should undertake a survey of the problem, the economic importance of different weeds, methods of control which had been already tried and their results, and so forth; his report to include recommendations for further co-operative work. The survey was undertaken by Mr. G. A. Currie, of the Division of Economic Entomology, assisted in certain aspects by Mr. J. Calvert, of the Division of Plant Industry. The report has been recently drawn up by Mr. Currie, and the more important portions of it are published by the Council for Scientific and Industrial Research of Australia in Pamphlet No. 60, "A Report on a Survey of Weed Problems in Australia" (Melbourne: Government Printer, 1936). Apart from the study made of past records of the activities and damage resulting from weeds, the weed legislation of each State was studied and the methods of administration ascertained. The pamphlet outlines the losses incurred from weeds, and the existing methods of control and the relation of dangerous weed growth to various primary industries. There is much in this pamphlet which could be studied with advantage in Great Britain. Among the sixteen weeds selected as being the most important in Australia are such well-known ones as bracken, stinkwort, thistles, blackberry, St. John's wort, lantana, ragwort, convolvulus and wild turnip.

NATURE

SUPPLEMENT

No. 3489 SATURDAY, SEPTEMBER 12, 1936 Vol. 138

The Impact of Science upon Society*

By Sir Josiah Stamp, G.C.B., G.B.E., F.B.A., President of the British Association

DURING the past year we have had to mourn the loss of our patron, King George V, but to rejoice in the honour done us by His Majesty King Edward VIII, himself our most illustrious past-president, in taking that office.

Since the beginning of this century the British Association has, till now, added only one new place of meeting in Great Britain to its list. Blackpool can certainly do for science in the North all that Bournemouth achieved in the South: give our record new vigour, and itself a new friend.

The reactions of society to science have haunted our presidential addresses with various misgivings for some years past. In his great centenary address General Smuts, answering the question "What sort of a world picture is science leading to?", declared that one of the great tasks before the human race is to link up science with ethical values and thus remove grave dangers threatening our future. For rapid scientific advance confronts a stationary ethical development, and science itself must find its most difficult task in closing a gap which threatens disruption of our civilization, and must become the most effective drive towards ethical values. In the following year a great engineer spoke as a disillusioned man, who watched the sweeping pageant of discovery and invention in which he used to take unbounded delight, and concluded by deploring the risk of losing that inestimable blessing, the necessity of toil and the joy of craftsmanship, declaring that spiritual betterment was necessary to balance the world. Then came the president of the Royal Society, a supreme biochemist, on the perils of a leisure made by science for a world unready for it, and the necessity for planning future adjustment in social reconstructions. Followed the astronomer, deploring man's lack of moral self-control; in knowledge man stands on the shoulders of his predecessor, whereas in moral nature they are on the same ground. The wreck of civilization is to be avoided by more and not by less science. Lastly, the geologist gloried in the greatest marvel of millions of centuries of development, the brain of man, with a cost in time and energy that shows us to be far from the end of a mighty purpose, and looking forward confidently to that further advance which alone can justify the design and skill lavished on such a task. So the geologist pleads then for scientific attention to man's mind. He has the same faith in the permanence of man's mind through the infinite range of years

"That oft hath swept the toiling race of men
And all their laboured monuments away",

that is shown at the Grand Canyon, where, at the point exposing, in one single view, over a billion and a half years of the world's geological history, a tablet is put to the memory of Stephen Tyng

---

* PRESIDENTIAL ADDRESS DELIVERED AT BLACKPOOL ON SEPTEMBER 9.

Mather, the founder of the National Park Service, bearing what is surely the most astonishing scientific expression of faith ever so inscribed :

> "There will *never come an end* to the good that he has done".

We have been pleading then in turn for ethical values, for spiritual betterment, for right leisure, for moral advance, and for mental development, to co-ordinate change in man himself with every degree of advance in natural science in such a harmony that we may at last call it 'progress'. This extension of our deeper concern beyond our main concern is not really new, but it has taken a new direction. I find that exactly one hundred years ago there was a full discussion on the moral aspects, a protest that physical science was not indeed, as many alleged, taking up so much of the attention of the public as to arrest its study of the mind, of literature and the arts ; and a round declaration that by rescuing scientists from the narrowness of mind which is the consequence of limiting themselves to the details of a single science, the Association was rendering "the prevailing taste of the time more subservient to mental culture". A study of these early addresses shows that we are more diffident to-day in displaying the emotions and ideals by which I do not doubt we are all still really moved. But they also show that we are preoccupied to-day with some of the results of scientific discovery of which they were certainly then only dimly conscious. A part of that field, which ought itself to become scientific, is my theme to-day.

IMPACT AS THE POINT OF CONTINUOUS CHANGE

What do we mean by impact ? My subject is *not* the influence or effect of science upon society —too vast, varied and indeterminate for such an occasion. We may consider the position of the average man, along a line of change we call 'progress', at the beginning of a certain interval of time and at its end. We might then analyse how much is due to a change in the average man himself, his innate physical and mental powers, and how much to other influences, and particularly to science. We may debate whether the distance covered is great or small by some assumed standard, and whether progress has been rapid. We might ask whether the direction has been right, whether he is happier or better—judged again by some accepted standard. But our concern here is with none of these questions. I ask whether the transition has been difficult and distressing, in painful jerks and uprootings, costly, unwilling, or unjust ; or whether it has been easy, natural, and undisturbing. Does society make heavy weather of these changes, or does it, as the policeman would say, 'come quietly' ?

The attitude of mind of our order may be either that change is an interruption of rest and stability, or that rest and stability are a mere pause in a constant process of change. But these alternatives make all the difference to its accommodating mechanisms. In one case there will be well-developed tentacles, grappling irons, anchorages, and all the apparatus of security. In the other, society will put on casters and roller bearings, cushions, and all the aids to painless transition. The *impact* of science will be surprising and painful in one case, and smooth and undamaging in the other. Whatever may be the verdict of the past, is society and its institutions now learning that change is to be a continuous function, and that meeting it requires the development of a technique of its own ?

Science itself has usually no immediate impact upon institutions, constitutions, and philosophies of government and social relations. But its *effects* on people's numbers, location and habits soon have ; and the resistance and repugnance shown by these institutions and constitutions to the changed needs may rebound or react through those effects upon scientific enterprise itself, and make it more precarious or more difficult. Thus the effect of applications of electricity and transport improvements is clearly to make the original areal extent of city or provincial Governments quite inappropriate, and the division of functions and methods of administration archaic. If these resist change unduly, they make it more difficult and frictional, and the applications of science less profitable and less readily acceptable. Time makes ancient good uncouth. When two bodies are violent or ungainly in impact, both may be damaged. If the written constitution of the United States, devised for the 'horse and buggy' days, still proves not to be amenable to adjustment for such demands, it will be difficult to overstate the repercussion upon economic developments and the scientific enterprise that originates them. Let any Supreme Court decision of unconstitutionality on the Tennessee Valley experiment in large-scale applied science to natural problems on a co-ordinated plan bear witness. Such unnecessary resistance may be responsible for much of what has been aptly called 'the frustration of science'.

Avoidable friction in the reception given to scientific discovery not only deprives the community of advantages it might otherwise have enjoyed much earlier, or creates a heavy balance of cost on their adoption ; it may also discourage applied science itself, making it a less attractive and worthwhile pursuit. In that sense we are considering also the impact of society upon science. This, too, is not new. The Association had as one of its first objects "to obtain a more general attention to the objects of Science, and a removal of any disadvantages of a public kind which impede its progress". The first address ever offered affirmed that the most effectual method of promoting science was the removal of the obstacles opposing its progress, and the president instanced the very serious obstacles in the science of optics due to the regulations relating to the manufacture of glass. To-day, perhaps the scientist places more stress upon the failure of Governments to encourage than upon their tendency to discourage. So much then for the *idea* of impact. Is the scientist or inventor responsible for impact, and if not, who is ?

THE QUESTION OF RESPONSIBILITY

Elsewhere I have retouched Jeremy Bentham's poignant picture of the inventor of over a century ago, plans and cap in hand, on the doorstep of the rich or influential, waiting for someone to believe in him. From this type of external 'sport' amongst engineers and scientists came much or most industrial innovation, external to the processes of business. To-day, in the older and applied sciences affecting industry, the solo scientist is the exception and, with the large research departments of particular businesses and trade research associations, the picture is quite different—the expenditure higher, but the results much more rapid and numerous, even if for a time they may be kept secret. Although records of finished work may be available over the civilized world, there is much overlapping of current work, but the price of this as a whole is a far smaller fraction of the total result, if we omit from our consideration the first-magnitude discoveries of epoch-making influence. The industrial community is now far more amenable than hitherto to scientific influence ; indeed it is often the instigator in the mass of minor advances.

The new epoch of concerted industrial research dates really from the end of the Great War. During all that time I have held some middle position of responsibility between the research laboratories and institutes on one hand, and the costing and profit and loss accounts on the other, and my impression is that the proportion of work in which the initiation comes from the business end is steadily increasing. In studies of the periods of scientific and industrial gestation respectively, I have elsewhere defined *scientific gestation* as the time elapsing between the first concept of the idea and its public presentation to society in a form substantially that in which it ultimately finds extensive use without important modification ; and *industrial gestation* as the period elapsing from this point to the date when in an economic or industrial sense the innovation is effective. Both periods are difficult to determine exactly in practice, but on a broad view, the period of industrial gestation, with which alone I am here concerned, appears to me certainly to have shortened materially, though possibly at greater social cost. It would obviously be so if industry is actively encouraging research. "Faraday's discoveries came at the beginning of the great steam era, and for fifty years there would have been no difference in transport, even if those discoveries had not been made", for the telegraph was the only material influence upon it, and practical lighting was delayed until 1900.

In nearly every scientific field there is subdivision of labour, and it is rare that the worker who digs out new truth 'at the face', so to speak, is also responsible for bringing it to the surface for the public use, still less for distributing the new scientific apparatus or ideas broadly, and even less for the profitable exploitation of the whole process. These functions are nearly always distinct, even though they are embraced under one general popular description : chemist, engineer, etc. But in few cases is it any part of the professional training in the subject itself, to study how new products or processes affect the structure or welfare of society. I have questioned many scientific workers, and find them, of course, keenly alive to the positive and direct beneficial effects of their work, but they have rarely any quantitative ideas as to negative, indirect and disturbing consequences.

All these discoveries, these scientific infants, duly born and left on the doorstep of society, get taken in and variously cared for, but on no known principle, and with no directions from the progenitors. Nor do the economists usually acknowledge any duty to study this phase, to indicate any series of tests of their value to society, or even of methods and regulation of the optimum rate of introduction of novelty. These things just 'happen' generally under the urge of profit, and of consumers' desire, in free competition, regardless of the worthiness of new desires against old, or of the shifts of production and, therefore, employment, with their social consequences. The economist rightly studies these when they happen, but he is not dogmatic about them not being allowed to happen at all in just that way on account of the social disturbance or degradation of non-economic values which they may involve. It is truly a 'no-man's-land', for it is rarely that the functions of government begin until a vested problem exists. Especially in Britain we do not anticipate—"Don't worry,—it may never happen".

Problems with us are usually called 'academic' until we are 'going down for the third time'. It is a maxim of political expediency not to look too far ahead, for it is declared that one will always provide for the wrong contingency. The national foresight over wireless was exceptional, and it has to be contrasted with the opportunist treatment of the internal combustion engine. In reply, it can, of course, be urged that no one can foresee just how a scientific idea will develop until it is tried out, rough and tumble, in economic society, and to make anticipatory rules may even hinder its development.

THE SCIENTIFIC WORKER IN THE WIDER FIELD

It is rightly stated that the training of the scientist includes no awareness of the social consequences of his work, and the training of the statesman and administrator no preparation for the potentiality of rapid scientific advance and drastic adjustment due to it, no prevision of the technical forces which are shaping the society in which he lives. The crucial impact is nobody's business.

When the research worker lifts his attention from his immediate pursuit and contemplates its hinterland, he has three possible areas of thought. He may dwell upon its practical applications and seek to make them as immediate and realistic as possible ; moved by the desire not to be merely academic, he may return to his task, to focus his attention primarily on what is likely to be of practical utility, rather than on what is intellectually intriguing. Or he may think of its ultimate social consequences, and speculate on the shifts in demand, the unemployment, the loss of capital, the ultimate raising of the standard of life that may result—in other words, he may engage in economic prevision and social and political planning for the results of his efforts. Or, in the third place, he may listen and watch for hints from other fields of scientific study which may react upon his own, and suggest or solve his problems. I do not attempt to give these priority. Economic and political prevision is the most difficult and precarious, because it needs a technique different from his own, and is not given by the light of Nature.

Specialist scientists have no particular gifts for understanding the institutional processes of social life, and the psychology of multiple and mass decisions. It is a tortuous and baffling art to transmute their exact findings into the wills and lives of unscientific millions. But quite a number engage in the pursuit, and have not much greater aptitude as amateur ministers of foresight than statesmen would have in planning research. Fewer are skilled, however, in what should be the most appropriate auxiliary to their work—the synthesizing of scientific knowledge. The more penetrating they are in their main pursuits, the less may they absorb through analogy or plain intimation from outside. We constantly hear that the average clinical application lags much farther behind the new resources of diagnosis from the laboratory than circumstances compel. But it may be the other way round. The strongest hint of the presence of a particular factor—a positive element in beriberi—was given by the clinician to the biochemist, who relied entirely on the *absence* of a particular factor, a negative element, no less than fifteen years before the biochemist took serious notice, looked for it, and found it. Bacteriology and chemistry await the advance of the biochemist before they come effectively to each other's assistance. The cause and prevention of the obstinate degree of maternal mortality are objects pursued *ad hoc*, with scarcely a casual glance at the direct appeal of the eugenist to observe the natural consequences of an improvement in female infant mortality two decades earlier.

I do not then pretend to dogmatize as to how far the scientist should become a social reformer. One physicist welcomes the growing sense of social responsibility, among some scientists at least, for the world the labours of their order have so largely created, though he deplores that in this field they are still utterly unscientific. Then another great authority, Sir Henry Dale, declares that it is the scientists' job to develop their science without consideration of the social uses to which their work might be put.

I have long watched the processes by which the scientific specialist 'makes up his mind' in fields of inquiry outside his own. It seems still a matter for investigation whether the development of a specialist's thinking, on balance, impairs or improves the powers of general thinking compared with what they might otherwise have been. We do not know the kind or degree of truth that may rest in Anatole France's aphorism : "The worst of science is, it stops you thinking". Perhaps this was more subtly expressed in the simpler words of the darkie mother : "If you haven't an education, you've jest *got* to use yoh brains".

My own experience is that when the attempt to deal with social consequences is made, we quickly find ourselves either in the field of larger politics debating the merits of the three prevalent forms of State government, or else performing miracles with fancy currencies and their blue prints reminiscent of the chemical engineer.

HUMAN ASPECTS OF CHANGING INDUSTRY

There are, however, some essential features of the impact which must be dealt with under any form of society and government, and with any machinery for regulating values. They involve man's abilities, his affections, and his tools, all of which have been brusquely treated in the past, and might be scientifically treated in the future. An industrial civilization is unthinkable without division, and, therefore, specialization, of labour, and without tools and capital instruments. Then life itself is not much worth living without social ties and the allegiances of place and kin. These three indispensable elements of the good life bring out defensive mechanisms for their protection. No one likes to see a man, highly trained for a special service or specially fitted by natural aptitudes, cut off from opportunity to use his powers and reduced to the level of an unskilled biped. No one likes to see the results of abstinence and specially directed labour which is embodied in a great machine or factory rendered impotent long before it has given its life's usefulness. Waste of skill and of capital are alike grave faults by which we should judge and condemn an industrial organization. Since man does not live by bread alone, if a ruthless industrial organization continually tears up the family from its roots, transferring it without choice to new surroundings, destroying the ties of kin, home and social life, of educational and recreational environments, it is far from ideal. Human labour can never be indefinitely fluid and transferable in a society that has a soul above consumption of mere commodities.

These three obstructions to change are not final and rigid limitations upon it. Men die, their skill and home associations with them. Plant and equipment wear out. Their successor presents a natural opportunity in each of the three cases for the introduction of change in position, in aptitude, in purpose or design, without waste or human distress. The length of working life and the durability of materials mark the natural phase or periodicity of a smoothly changing society —its quanta, so to speak. But the impetus for change or the irritant has no such intervals. It proceeds from various causes: varying harvests, changes in natural forces; changing human desires and fashions; differences in the rate of growth of population in its different parts; the collective psychological errors of optimism and pessimism in business in an individualistic society; variations in gold supplies and credit policies based thereon. All or any of these, without invoking any disturbances from the impact of scientific discovery, would serve to make adjustments necessary outside the natural phases to which I have referred, in a society with parts that are interdependent through division of labour, and localization of industry, joined by foreign trade and convenient transport. These alone would bring about a changing world with incomplete adaptations, loss of capital, and so-called frictional unemployment.

It is easy to exaggerate the adjustment necessary for the addition of invention and science to these causes of change. But with the intensification of scientific effort, and the greater sub-division of industry, the possible dislocation becomes more frequent, and the ways of meeting such change of greater public importance. This field of inquiry includes widely diverse questions, for example, patent laws, invention clearing, obsolescence accountancy and costing regulation, taxation adjustments, local rating pooling, trade union regulations, price controls, technical education, age and other discriminations in unemployment relief, transfer bonuses, pension rights, housing facilities, and more selective direction of financial support of intensive scientific research. In this neutral field the specialist scientist and the politician are both amateurs. It is to be covered by each extending his studies, and by specialists who treat impact and change as an area of scientific study.

I do not propose to go over all the ground, so old, so constantly renewed, as to the effect of machinery upon employment. It is known as a historical induction that, in the long run, it makes more employment than it destroys, in providing work in making the machinery, in reducing price so that far greater quantities of the commodity concerned may be consumed, and in enabling purchasing power to be diverted to increase other productions. It has even facilitated the creation of a larger population, which in turn has provided the new markets to work off the additional potentiality of the machinery. It does all this in 'the long run'; but man has to live in the 'short run', and at any given moment there may be such an aggregation of unadjusted 'short runs' as to amount to a real social hardship. Moreover, it comes in this generation to a people made self-conscious by statistical data, repeated widespread at frequent intervals, and to a people socially much more sensitive to all individual hardship and vicissitude which is brought about by communal advance.

THE 'BALANCE OF INNOVATION' AND POPULATION

There are two important aspects of the change induced by science which are insufficiently realized, and which make a profound difference to the direction of thought and inquiry. The first I will call the 'balance of innovation' and the second the 'safety valve' of population.

The changes brought by science in economic life may be broadly classified as the 'work creators' and the 'work savers'. The latter save time, work and money by enabling the existing supply of particular commodities to be produced more easily, and therefore at lower cost, and finally at lower prices. People can spend as much money as before upon them and get larger quantities, or they can continue to buy their existing requirements at a lower cost. In this second event they 'save money' and their purchasing power is released for other purposes. By a parallel process, producing or labouring power is released through unemployment. The released working force and released purchasing power can come together again in an *increased* demand for other products which, to this extent, have not been hitherto within effective demand. The supply of this increase may go part or all of the way to absorb the displaced labour. But this process takes time, and the labour displaced is not at once of the right kind or in the right place. More important, however, is the invention of quite new objects of public demand, which may be desired in addition to the supply of old ones. This brings together released labour and released purchasing power in the most decisive way.

The most orderly and least disturbing phases of progress will be found when these two types of innovation are reasonably balanced. Of course, few new objects of purchasing ambition are entirely additive; most of them displace some other existing supplies. Artificial silk displaces some cotton consumption, radio may displace some types of musical instruments. Recently the German production of pianos and guitars has been at a very low percentage of capacity, and part of this has been made good by the demand for radio sets. The dislocations caused by labour-saving machinery can most easily be made good by a due *balance* of new labour-creating commodities.

A natural increase of population is the best shock absorber that the community can possess, especially if accompanied by an extension of territory such as the United States enjoyed in the constant westward movement of the frontier in the nineteenth century, or Britain in the period of overseas emigration. A moment's reflection will show why this is the case. Assume that 1,000,000 units of a commodity are made by 100,000 men, and that there is an increase of population of 2 per cent per annum, so that in five years 1,100,000 units will be consumed and employ 110,000 men. Now assume the introduction of a new invention which enables 1,100,000 units to be made by 100,000 men. There will be no displacement of existing labour, but only a redirection of new and potential labour from that industry to other fields. Again, a considerable reduction in demand *per head* can be sustained without dislocation, if the actual aggregate of production demanded is maintained by increasing numbers. The affected industry can remain static and need not become derelict. New entrants to industry will be directed to those points where purchasing power, released through labour-saving devices, is creating new opportunity with new products. New capital is also naturally directed into the new channels, instead of into additions to the old industry.

Now the problem before all Western industrial countries is the fact that their populations are shortly becoming stationary (and then will begin to decline noticeably) and this safety valve of increasing population will no longer be available. Every transfer of *per capita* purchasing power to new directions must then be a definite deduction from the old directions, no longer made good by the steady increase in the numbers demanding less per head from those old sources. The impact of science upon a stationary population is likely, *ceteris paribus*, to be much more severely felt than upon a growing population, because the changes of direction cannot be absorbed by the newly directed workers. Of course, the effects of a static population can be mitigated if the *per capita* income is increasing, because a new direction of demand can be satisfied out of the additional purchasing power without disturbing the original directions of demand provided by the original purchasing power.

The change from a growing to a static or declining population is only one type of difficulty. While the aggregate is altering but slowly, the parts may be changing rapidly. Thus, in Great Britain, 40·4 millions in 1937 becomes 40·6 in 1942, 40 in 1947, 39·8 millions in 1952, 38·9 in 1957 and 37·5 in 1962. But the children aged sixteen years—which I take because of its influence on schools, teaching and industrial entry—have been estimated, taking those in 1937 as 100, to be 85 in 1942, 73 in 1952 and 62 in 1962. A fall of this magnitude means that industries and institutions dependent upon the present numbers must not be merely static but actually regressive. On the other hand, the old people from sixty-five to seventy-four years will increase in this ratio—100, 113, 127, and 133. These problems of static populations at home are accentuated by the possibility of a similar tendency abroad, and need thought in advance. The Australian farmer is more affected by the British conditions of population than by his own.

We have thus the first difficulty, that of a static total demand, the second, that the safety valve of new industrial entrants is becoming smaller, but a third difficulty comes from the present tendency of that class. A stationary elderly population must be very inflexible to change, but a stream of new young life, even if it is to be smaller, would give the opportunity for just that change of direction, in training and mobility, which society needs. But unfortunately, in practice this does not now seem to be very adaptable. For we learn from certain Unemployment Insurance areas that while the older people will willingly take jobs at wages a few shillings in excess of the unemployment relief, the younger men are more difficult. For every one that will accept training under good conditions to suit them for eligible work, ten may refuse, and the number who will not go any distance to take work at good wages is also in excess of those who do. Attachment to place for older people is understandable, and has been accentuated by housing difficulties—one learns of miners unemployed in a village where the prospects of the pit reopening are negligible, while at the same time, only twenty miles away, new miners are being created by attraction from agriculture to more extended workings in their area. The very social machinery which is set up to facilitate change or to soften dislocation aggravates the evil. The first two difficulties are unalterable. This third difficulty is a subject for scientific examination.

INDUSTRIAL DISEQUILIBRIUM

So much for the effect of change of any kind upon employment. Now let us narrow this to scientific changes. At any given moment the impact of science is always causing some unemployment, but at that same time the constructive additional employment following upon past expired impacts is being enjoyed. But it is easy to exaggerate the amount of the balance of net technological unemployment. For industrial disequilibrium arises in many ways, having nothing whatever to do with science. Changes of fashion, exhaustion of resources, differential growth in population, changing customs and tariffs, the psychological booms and depressions of trade through monetary and other causes, all disturb equilibrium, and, therefore, contract and expand employment in particular places.

Our analytical knowledge of unemployment is bringing home the fact that, like capital accumulation, it is the result of many forces. A recent official report indicated that a quite unexpected amount or percentage of unemployment would be present even in boom times. We know already that there may be a shortage of required labour in a district where there is an 8 or 10 per cent figure of unemployment. So, in Great Britain there may well be a million unemployed in what we should call good times—it is part of the price we pay for the high standard of life secured by those who retain employment. For a level of real wage may be high enough to prevent every one being employable at that wage—though that is by no means the whole economic story of unemployment. Of this number, probably 200,000 would be practically unemployable on any ordinary basis—the 'hard core' as it is called. Perhaps seven or eight hundred thousand form the perpetual body, changing incessantly as to its unit composition, and consisting of workers undergoing transition from job to job, from place to place, from industry to industry, with seasonal occupations—the elements of 'frictional' unemployment through different causes. Out of this number, I should hazard that not more than 250,000 would be unemployed through the particular disturbing element of net scientific innovation.

This is the maximum charge that should be laid at the door of science, except in special times, such as after a war, when the ordinary application of new scientific ideas day by day has been delayed, and all the postponed changes tend to come with a rush. At any given moment, of course, the technological unemployment that could be computed from the potentiality of new processes over displaced ones appears to be much greater. But such figures are *gross*, and from them must be deducted all recent employment in producing new things or larger production of old things, due to science. If we are presenting science with part of the responsible account of frictional unemployment at any moment, it will be the total technological reduction due to new processes and displacement due to altered directions of demand, less the total new employment created by new objects of demand. This has to be remembered when we are being frightened by the new machine that does with one man what formerly engaged ten. Perhaps birth control for people demands ultimately birth control for their impedimenta.

The rate of introduction of new methods and the consequent impact upon employment may depend upon the size and character of the business unit. If all the producing plants for a particular market were under one control, or under a coordinated arrangement, the rate of introduction of a new labour-saving device will be governed by a simple consideration. It can be introduced with each renewal programme for each replacement of an obsolete unit, and therefore without waste of capital through premature obsolescence. But this applies only to small advantages. If the advantages are large, the difference in working costs for a given production between the old and the new types may be so considerable that it will meet not only all charges for the new capital, but also amortize the wasted life of the assets displaced before they are worn out. In neither case then is there any waste of capital, and the absorption of the new idea is orderly in time. But it is quite otherwise if the units are in different ownerships. Excess capacity can quickly result from new ideas. A new ship or hotel or vehicle with the latest attractions of scientific invention, quite marginal in their character, may obtain the bulk of the custom, and render half empty and, therefore, half obsolete, a unit built only a year before. The old unit has to compete by lower prices, and make smaller profits. The newer unit is called upon to bear no burdens in aid of the reduced capital values of the old. It may be that the enhanced profits of the one added to the reduced profits of the other make an average return upon capital not far different from the average that would result in a community where orderly introduction on a renewal basis is the rule. Or perhaps the community gets some of its novelties rather earlier under competitive conditions, and pays a higher rate of interest for them as a net cover for the risks of obsolescence. Waste of capital would be at a minimum if the 'physical' life before wearing out were as short as the 'social' life of the machine. To make a thing so well that it will last 'for ever' is nothing to boast about if it will be out of fashion in a few years.

Scientists often look at the problem of practical application as if getting it as rapidly as possible were the only factor to be considered in social advantage, and this difference in the position of monopoly or single management in their ability to 'hold up' new ideas is treated as a frustration in itself. Thus it has been said "the danger of obsolescence is a great preventative of fundamental applications to science. Large firms tend to be excessively rigid in the structures of production". Supposing that the obsolescence in question is a real factor of cost, it would fall to be reckoned with in the computation for transition, whatever the form of society, and even if the personal 'profit' incentive were inoperative. It cannot be spirited away. A customary or compulsory loading of costs for short-life obsolescence would retard uneconomically rapid competition of novelties and could be scientifically explored.

The Charge for Displaced Labour

Now let us look at displaced labour and the costs of it. If the effect of diversion of demand through invention is to reduce the scope or output of particular industries or concerns in private management, they have no option but to reduce staff. If the pressure is not too great, or the change too rapid, this does not necessarily result in dismissals, for the contraction of numbers may be made by not filling up, with young people, the vacancies caused by natural wastage, through death and retirement. But where dismissals are inevitable, re-engagements may take place quickly in the competing industries, otherwise unemployment ensues. Any resulting burden does not fall upon the contracting and unprofitable industry —it has troubles enough of its own already. Nor is it put upon the new and rising industry, which is attracting to itself the transferred profits. In the abstract, it might be deemed proper that before the net gains of such an industry are computed or enjoyed it should bear the burdens of the social dislocation it causes by its intrusion into society. In practice, it would be difficult to assess its liability under this head, and in fact even if it could be determined, new industries have so many pioneer efforts and losses, so many failures, so many superseded beginnings, that it might well be bad social policy to put this burden upon them, for they would be discouraged from starting at all, if they had to face the prospect of such an overhead cost whatever their results.

It would, of course, be theoretically possible to put a special levy on those new industries that turned out to be profitable, and to use it to relieve the social charges of dislocation of labour. But much the same argument could be used for the relief of obsoletism of capital. The distinction would, however, be that in the case of the capital it could be urged that the investor should have been wide enough awake to see the possibilities of the rival, whereas the worker, induced to take up employment in such a superseded industry, was a victim, and could not be expected to avoid it by prevision. In any event, the prevailing sentiment is rather to encourage developing industries, than to put special burdens upon them, in order that the fruits of science may be effectively enjoyed by society with as little delay as possible.

In the upshot, therefore, the injuries to labour, though not to capital, are regarded as equitably a charge to be borne by society in general through taxation, and to be put upon neither the causing nor the suffering business unit.

It may well be assumed that, taken throughout, the gains of society as a whole from the rapid advance are ample enough to cover a charge for consequential damages. But society is not consciously doing anything to regulate the rate of change to an optimum point in the net balance between gain and damage.

The willingness of society to accept this burden is probably mainly due to the difficulty of fairly placing it, for we find that when it *can* actually be isolated and the community happens fortuitously to have a control, or the workers a power to induce, it will be thrown, not upon the attacking industry, if I may so call it, but upon the defender. Thus in the United States recently, the price of consent to co-ordinating schemes made for the railroads to reduce operating expenses has been an agreement on this very point. If staff is dismissed, as it was on a large scale in the depression, because of fewer operations and less stock in consequence of reduced carriage through the smaller volume of trade, or through road and sea competition, no attempt was made to put any of the social cost upon the railroads, and the dismissed staff become part of the general unemployed. But if the self-defence of the companies against competition takes the form of co-operation with each other to reduce operations and stock and, therefore, costs, any resultant dismissals are made a first charge upon them.

The agreement is elaborate, and has the effect of preventing any adjustments which an ordinary business might readily make when it throws the burden on society, unless those adjustments yield a margin of advantage large enough to pay for their particular special effects. Thus the rapidity of adjustment to new conditions, not to meet the case of higher profits to be made at the expense of workers, but rather to obviate losses through new competition, is materially affected, and a brake is put upon the mechanism of equilibrium in this industry which does not exist in its rivals, or in any others where the power exists to throw it upon the community. A similar provision exists in the Argentine, and it is imposed by Act of Parliament in Canada, but as one of the concerns is nationally owned, and the current losses fall upon the national budget, its charge is really socially borne in the end.

In Great Britain such provisions were part of the amalgamation project of 1923, and of the formation of a single transport authority in London in 1933, and, therefore, did not arise through steps taken to meet new factors of competition. But the opportunity for their imposition came when rights to road powers and rights to pooling arrangements were sought by the railways —both of them adjusting mechanisms to minimize the losses due to the impact of new invention— and this was clearly a specialized case of keeping the burdens off society. In the case of the electricity supply amalgamation of 1933, brought about for positive advantages rather than in defence against competition, similar provision was made, and parliamentary powers for transfers to gas and water undertakings, also not defensive against innovation, have been accompanied by this obligation. In the case of such uncontrolled businesses as Imperial Chemicals and Shell Mex, rationalizing to secure greater profits, rather than fighting rearguard actions to prevent losses, obligations to deal with redundancies have been voluntarily assumed. In such cases the public obloquy of big business operations inimical to society can be a negative inducement, but some freedom from radical competition in prices provides a positive power to assume the burden initially, and pass it forward through price to consumers, rather than back against shareholders. The third case, however, of making it a net charge on the improved profits, is quite an adequate outlet. If the principle of putting this particular obstacle in the way of adjustments to meet new competition (as distinct from increasing profits) is socially and ethically correct, it is doubtful whether it is wisely confined to cases where there is quite fortuitously a strategic control by public will.

It will be clear that the difference between the introduction by purely competitive elements involving premature obsolescence and unemployment, and by delayed action, is a cost to society for a greater promptness of accessibility to novelty. The two elements of capital and labour put out of action would have supplied society with an extra quantity of existing classes of goods, but society prefers to forgo that for the privilege of an earlier anticipation of new things. I estimate this price to be of the order of 3 per cent of the annual national income. But when we speak of social advantage, on balance, outweighing social cost, we dare not be so simple in practice. If the aggregate individual advantage of adopting some novelty is $100x$ and the social cost in sustaining the consequential unemployed is $90x$, it does not follow that it is a justifiable bargain for society. The money cost is based on an economic minimum for important reasons of social repercussions. But the moral effects of unemployment upon the character and happiness of the individual escape this equation altogether, and are so great that we must pause upon the figures. What shall it profit a civilization if it gain the whole world of innovation and its victims lose their souls ?

So far I have treated the problem of innovation as one of uneconomic rapidity. But there is another side—that of improvident tardiness. Enormous potentialities are seen by scientists waiting for adoption for human benefit, under a form of society quicker to realize their advantage, readier to raise the capital required, readier to pay any price for dislocation, and to adjust the framework of society accordingly. A formidable list of these potentialities can be prepared, and there is little doubt that with a mentality adjusted for change, society could advance much more rapidly. But there is a real distinction between the methods of adopting whatever it is decided to adopt, and the larger question of a more thoroughgoing adoption.

In proportion as we can improve the impact of the present amount of innovation, we can face the problem of a larger amount or faster rate. Unless most scientific discoveries happen to come within the scope of the profit motive, and it is worth someone's while to supply them to the community, or unless the community can be made sufficiently scientifically minded to include this particular demand among their general commercial demands, or in substitution for others, nothing happens—the potential never becomes actual. It has been computed that a benevolent dictator could at a relatively small expense, by applying our modern knowledge of diet, add some two inches to the average stature, and seven or eight pounds to the average weight of the general population, besides enormously increasing their resistance to disease. But dictators have disadvantages, and most people prefer to govern their own lives indifferently, rather than to be ideal mammals under orders. To raise their own standard of scientific appreciation of facts is the better course, if it is not Utopian. It has been clear for long enough that a diversion of part of the average family budget expenditure from alcohol to milk would be of great advantage. But it has not happened. If the individual realized the fact, it certainly might happen. It is ironically remarked that the giving of free milk to necessitous children, with all the net social gain that it may bring about, has not been a considered social action for its own sake, but only the by-product emergency of commercial pressure—not done at the instance of the Ministry of Health or the Board of Education, but to please the Milk Marketing Board by reducing the surplus stocks of milk in the interests of the producer!

PLANNING AND ITS LIMITATIONS

Scientists see very clearly how, if politicians were more intelligent, if business men were more disinterested, and had more social responsibility, if Governments were more fearless, far-sighted, and flexible, our knowledge could be more fully and quickly used to the great advantage of the standard of life and health—the long lag could be avoided, and we should work for social ends. It means, says Dr. Julian Huxley, "the replacement of the present socially irresponsible financial control by socially responsible planning bodies". Also, it obviously involves very considerable alterations in the structure and objectives of society, and in the occupations and pre-occupations of its individuals.

Now a careful study of the literature of planning shows that it deals mainly with planning the known, and scarcely at all with planning for changes in the known. Although it contemplates 'planned' research, it does not generally provide for introducing the results of new research into the plan, and for dealing with the actual *impact*—the unemployment, redirection of skill, and location, and the breaking of sentimental ties that distinguish men from robots. It seems to have not many more expedients for this human problem than our quasi-individualist society with its alleged irresponsibility. It also tends to assume that we can tell in advance what will succeed in public demand and what will be superseded. There is nothing more difficult, and the attempt to judge correctly under the intellectual stimulus of high profits and risk of great losses is at least as likely to succeed as the less personally vital decision on a committee. Would a planning committee, for example, planning a new hotel in 1904, have known any better than capitalist prevision that the fifteen bathrooms then considered adequate for social demand ought really to have been ten times that number if the hotel was not to be considered obsolete thirty years later? Prevision thought of in terms of hindsight is easy, and few scientists have enjoyed the responsibility of making practical decisions as to what the public will want far ahead. They, therefore, tend to think of prevision in terms of knowledge and appreciation of particular scientific possibilities, whereas it involves unknown demand schedules, the unceasing baffling principle of substitution, the inertia of institutions, the crusts of tradition and the queer incalculability of mass mind. Of course, in a world where people go where they are told, when they are told, do what they are instructed to do, accept the reward they are allotted, consume what is provided for them, and what is manifestly so scientifically 'good for them', these difficulties need not arise. The human problem will then be the 'impact of planning'.

I am not here examining the economics of planning as such, but only indicating that it does not provide automatically the secret of correct prevision in scientific innovation. When correct prevision is possible, a committee can aim at planning with a minimum disturbance and wastage (and has the advantage over individuals acting competitively), but for such innovation as proves to be necessary it does not obviate the human disturbance or radically change its character. The parts of human life are co-ordinated and some are more capable of quick alteration than others, while all are mutually involved. One may consider the analogy of a railway system which has evolved, partly empirically and partly consciously, as a co-ordinated whole. Suddenly the customary speed is radically changed, and then it may be that all the factors are inappropriate—distance between signals, braking power, radius of curves, camber or super-elevation, angles of crossings, bridge stresses. The harmony has been destroyed. Especially may this be the case if the new factor applies to some units only, and not to all, when the potential density of traffic may be actually lessened. The analogy for the social system is obvious, and its form of government matters little for the presence of the problem, though it may be important in the handling of it.

I have spoken as though the normal span of life of men and machinery themselves provides a phase to which scientific advance might be adjusted for a completely smooth social advance. But this would be to ignore customs and institutions, even as we see in Federal America, Australia and Canada, constitutions which lengthen that phase and make it less amenable as a natural transition. At one time we relied on these to bring about the economic adjustment necessary. But technical changes take place so rapidly that such forces work far too slowly to make the required adaptation. Habits and customs are too resistant to change in most national societies to bring about radical institutional changes with rapidity, and we patch with new institutions and rules to alleviate the effects rather than remove the causes of maladjustments. The twenty mile speed limit long outstayed its fitness, and old building restrictions remained to hamper progress. Edison is reported to have said that it takes twenty-five years to get an idea into the American mind. The Webbs have given me a modal period of nineteen years from the time when an idea comes up as a practical proposition from a 'dangerous' left wing to the date when it is effectively enacted by the moderate or 'safe' progressive party. This period of political gestation may be a function of human psychology or of social structure. We do not know how ideas from a point of entry permeate, infiltrate or saturate society, following the analogues of conduction, convection, or lines of magnetic force.

Our attitude of mind is still to regard change as the exceptional, and rest as the normal. This comes from centuries of tradition and experience, which have given us a tradition that each generation will substantially live amid the conditions governing the lives of its fathers, and transmit those conditions to the succeeding generation. As Whitehead says: "we are living in the first period of human history for which this assumption is false". As the time span of important change was considerably longer than that of a single human life, we enjoyed the illusion of fixed conditions. Now the time span is much shorter, and we must learn to experience change ourselves.

CULTURAL LAGS IN A DYNAMIC SOCIETY

I have so far discussed modification of impact to meet the nature of man. Now we must consider modifying the nature of man to meet impact.

Sociologists refer to our 'cultural lags' when some of the phases of our social life change more quickly than others and thus get out of gear and cause maladjustments. Not sufficient harm is done to strike the imagination when the change is a slow one, and all the contexts of law, ethics, economic relations and educational ideals tend towards harmony and co-ordination. We can even tolerate, by our conventions, gaps between them, while preachers and publicists can derive certain amusement and profit from pointing out our inconsistencies. But when things are moving very rapidly, these lags become important; the concepts of theology and ethics, the tradition of the law, all tend to lag seriously behind changes brought about through science, technical affairs and general economic life. Some hold that part of our present derangement is due to the lack of harmony between these different phases—the law and governmental forms constitutionally clearly lag behind even economic developments as impulsed by scientific discovery. An acute American observer has said that "the causes of the greatest economic evils of to-day are to be found in the recent great multiplication of interferences by Government with the functioning of the markets, under the influence of antiquated doctrines growing out of conditions of far more primitive economic life". It would be, perhaps, truer to say that we are becoming 'stability conscious', and setting greater store, on humanitarian grounds, by the evil effects of instability.

In the United States it would be difficult to find, except theoretically in the President, any actual person, or instrument in the constitution, having any responsibility for looking at the picture of the country as a whole, and there is certainly none for making a co-ordinated plan. Indeed, in democracy, it is difficult to conceive it, because the man in public life is under continual pressure of particular groups, and so long as he has his electoral position to consider, he cannot put the general picture of progress in the forefront. Whitehead declared that when an adequate routine, the aim of every social system, is established, intelligence vanishes and the system is maintained by a co-ordination of conditioned reflexes. Specialized training alone is necessary. No one, from President to miner, need understand the system as a whole.

The price of pace is peace. Man must move by stages in which he enjoys for a space a settled idea, and thus there must always be something which is rather delayed in its introduction, and the source of sectional scientific scorn. If every day is 'moving day', man must live in a constant muddle, and create that very fidget and unrest of mind which is the negation of happiness; always 'jam to-morrow'—the to-morrow that 'never comes'. If we must have quanta or stages, the question is their optimum length and character, not merely the regulation of industry and innovation to their tempo, but also the education of man and society to pulse in the same rhythmic wave-length or its harmonic.

THE BALANCE OF PHYSICAL AND BIOLOGICAL SCIENCES

In some ways we are so obsessed with the delight and advantage of discovery of new things that we have no proportionate regard for the problems of arrangement and absorption of the things discovered. We are like a contractor who has too many men bringing materials on to the site, and not enough men to erect the buildings with them. In other words, if a wise central direction were properly allocating research workers to the greatest marginal advantage, it would make some important transfers. There is not too much being devoted to research in physics and chemistry, as modifying industry; but there is too much relatively to the research upon the things they affect, in physiology, psychology, economics, sociology. We have not begun to secure an optimum balance. Additional financial resources should be applied more to the biological and human sciences than to the applied physical sciences, or possibly, if resources are limited, a transfer ought to be made from one to the other.

Apart from the superior tone sometimes adopted by 'pure science' towards its own applications, scientific snobbery extends to poor relations. Many of the hard-boiled experimental scientists in the older and so productive fields look askance at the newer borderline sciences of genetics, eugenics and human heredity, psychology, education, and sociology, the terrain of so much serious work but also the happy hunting ground of 'viewey' cranks and faddists. Here the academic soloist is still essential, and he has no great context of concerted work into which to fit his own. But unless progress is made in these fields which is comparable with the golden ages of discovery in physics and chemistry, we are producing progressively more problems for society than we are solving. A committee of population experts has recently found that the expenditure on the natural sciences is some eight to ten times greater than that on social sciences. There is scarcely any money at all available for their programme of research into the immense and vital problems of population in all its qualitative and quantitative bearings. An attack all along the front from politics and education to genetics and human heredity is long overdue. Leisure itself is an almost unexplored field scientifically. For we cannot depend wholly on a hit and miss process of personal adaptation, great though this may be.

There must be optimal lines of change which are scientifically determinable. We have seen in a few years that the human or social temperament has a much wider range of tolerance than we had supposed. We can take several popular examples. The reaction to altered speed is prominent. In the "Creevey Papers", it is recorded that the Knowsley party accomplished 23 miles per hour on the railway, and recorded it as "frightful—impossible to divest yourself of the notion of instant death—it gave me a headache which has not left me yet—some damnable thing must come of it. I am glad to have seen this miracle, but quite satisfied with my first achievement being my last". At the British Association meeting of 1836, an address on railway speeds prophesied that some day 50 miles an hour might be possible. Forty years ago we may remember that a cyclist doing 15–18 miles an hour was a 'scorcher' and a public danger. Twenty-five years ago, 30 miles an hour in motoring was an almost unhealthy and scarcely bearable pace. To-day the fifties and sixties are easily borne, both by passenger and looker-on. Aeroplane speeds are differently judged, but at any rate represent an extension of the tolerance. Direct taxation thirty years ago in relation to its effect on individual effort and action seemed to reach a breaking-point and was regarded as psychologically unbearable at levels which to-day are merely amusing. The copious protection of women's dress then would have looked upon to-day's rationality as suicidal lunacy.

One hesitates to say, therefore, that resistances to scientific changes will be primarily in the difficulty of mental and physical adjustments. But there can be little doubt that with the right applications of experimental psychology and adjusted education, the mind of man would be still more adaptable. Unfortunately, we do not know whether education as an acquired characteristic is in any degree inheritable, and whether increasing educability of the mass is a mere dream, so that we are committed to a Sisyphean task in each generation. Nor do we know whether this aspect is affected by the induced sterility of the age. It may not be a problem of changing the same man in his lifetime, but of making a larger difference between father and son. The latest teachings of geneticists hold out prospects for the future of man which we should like to find within our present grasp, and recent successful experiments with mammals in parthenogenesis and eutelegenesis bear some inscrutable expression which may be either the assurance of new hope for mankind or a devil's grin of decadence.

THE NEW ECONOMICS

What is economics doing in this kaleidoscope ?

The body of doctrine which was a satisfactory analysis of society twenty-five years ago is no longer adequate, for its basic postulates are being rapidly changed. It confined itself then to the actual world it knew and did not elaborate theoretical systems on different bases which might never exist. It is, therefore, now engaged in profoundly modifying the old structures to meet these new conditions. Formerly it assumed, quite properly, a considerable degree of fluid or competitive adjustment in the response of factors of production to the stimulus or operation of price, which was really a theory of value-equilibrium. Wherever equilibrium was disturbed, the disturbance released forces tending to restore it. To-day many of the factors formerly free are relatively fixed, such as wage-levels, prices, market quotas, and when an external impact at some point strikes the organism, instead of the effect being absorbed throughout the system by adjustments of all the parts, it now finds the shock evaded or transmitted by many of them, leaving the effects to be felt most severely at the few remaining points of free movement or accommodation. Unemployment is one of these. The extent to which this fact throws a breaking strain upon those remaining free points is not completely analysed, and the new economics of imperfect competition is not fully written out or absorbed. The delicate mechanism of price adjustment with the so-called law of supply and demand governed the whole movement, but with forcible fixation of certain price elements consequences arise in unexpected and remote quarters. Moreover, the search for a communally planned system to secure freedom from maladjustments involves a new economics in which the central test of price must be superseded by a statistical mechanism and a calculus of costs which has not yet been satisfactorily worked out for a community retaining *some* freedom of individual action and choice.

The old international currency equilibrated world forces and worked its way into internal conditions in order to do so. But the modern attempt to prevent any internal effect of changes in international trade, or to counteract them, and the choice of internal price stability at all costs against variable international economic equations, has set economic science a new structure to build out of old materials. At this moment when elasticity is most wanted, stability leading to rigidity becomes a fetish. The aftermath of war is the impossibility of organizing society for peace.

The impact of economic science upon society to-day is intense and confusing, because, addressing itself to the logic of various sets of conditions as the likely or necessary ones according to its exponents' predilections, it speaks with several voices, and the public are bewildered. Unlike their claims upon physics and mathematics, since it is dealing with money, wages and employment, the things of everyday, they have a natural feeling that it ought to be easily understandable and its truth recognizable. Balfour once said, in reference to Kant, "Most people prefer a problem which they cannot explain, to an explanation which they cannot understand". But in the past twenty years, the business world and the public have become economics-conscious, and dabble daily in index numbers of all kinds, and the paraphernalia of foreign exchange and statistics of economic life. The relativity of economic principle to national psychology baffles the economists themselves, for it can be said truly at one and the same time, for example, that confidence will be best secured by balancing the Budget, and by not balancing it, according to public mentality.

The economics of a community not economically self-conscious are quite different from those of a people who watch every sign and act accordingly. Thus the common notion that economics should be judged by its ability to forecast (especially to a particular date) is quite fallacious, for the prophecy, if 'true' and believed, must destroy itself, inasmuch as the economic conduct involved in the forecast is different after the forecast from what it would have been before. The paradox is just here, for example : if a people are told that the peak of prices in a commodity will actually be on June 10, they will all so act that they anticipate the date and destroy it. Economics, thoroughly comprehended, can well foretell the effects of a tendency, but scarcely ever the precise date or amount of critical events in those effects. The necessity for a concentration upon new theoretical and analytical analysis, and upon realistic research, is very great. But so also is the need for widespread and popular teaching. For a single chemist or engineer may by his discovery affect the lives of millions who enter into it but do not understand it, whereas a conception in economic life, however brilliant, generally requires the conformity of the understanding and wills of a great number before it can be effective.

THE SCIENCE OF MAN

But not alone economics: if the impact of science brings certain evils, they can only be cured by more science. Ordered knowledge and principles are wanted at every point. Let us glance at three only, in widely different fields: man's work, man's health, man's moral responsibility. The initial impact of new science is in the factory itself. The kind of remedy required here is covered by the work of the National Institute of Industrial Psychology. Some of this improves upon past conditions, some creates the conditions of greater production, but much of it combats the evils arising from new conditions created by modern demands, speed, accuracy and intensity. It invokes the aid of many branches of science. It is the very first point of impact. Yet its finance is left to personal advocacy, and commands not 10 per cent of the expenditure on research in artificial silk, without which the world was reasonably happy for some centuries. We can judge of the scope of this by the reports of the Industrial Health Research Board.

Again, the scientific ancillaries of medicine have made immense strides. Clinical medicine as an art makes tardy, unscientific and halting use of them. The public remain as credulous as ever, their range of gullibility widened with every pseudo-scientific approach. (We do not know what proportion of positive cases can create the illusion of a significant majority in mass psychology, but I suspect that it is often as low as twenty per cent.) For a considerable range of troubles inadequately represented in hospitals, the real experience passes through the hands of thousands of practitioners, each with too small a sample to be statistically significant, and is, therefore, wasted from a scientific point of view. Half-verified theories run riot as medical fashions, to peter out gradually in disillusionment. If the scattered cases were all centralized through appropriately drawn case-histories, framed by a more scientifically trained profession, individual idiosyncrasy would cancel out, and mass scrutiny would bring the theories to a critical statistical issue of verification or refutation in a few months. This would be to the advantage of all society, and achieve an even greater boon in suggesting new points for central research.

A suggestion has been made for an inventions clearing house, to "co-operate the scientific, social and industrial phases of Invention, and to reduce the lag between invention and application" managed by a committee of scientists and a committee of industrialists and bankers. The proposal came to me from New York, but London was to be the home of the organization, which was to adopt a code of ethics in the interests of inventors, industry and *social progress*. This brings me to my third example, the field of ethics, which needs the toil of new thought. The systems of to-day, evolving over two thousand years, are rooted in individualism and the relations between individuals. But the relations of society to-day are not predominantly individual, for it is permeated through and through with corporate relations of every kind. Each of these works over some delegated area of the individual's choice of action, and evolves a separate code for the appropriate relationship. The assumption that ethical questions are decided by processes which engage the individual's whole ethical personality is no longer even remotely true. The joint stock company may do something, or refrain from doing something, on behalf of its shareholders, which is a limited field of ethics, and may but faintly resemble what they would individually do with all other considerations added to their financial interests. The whole body of ethics needs to be reworked in the light of modern corporate relations, from Church and company, to cadet corps and the League of Nations.

In no case need we glorify change: but true rest may be only ideally controlled motion. The modern poet says:

> "The endless cycle of idea and action,
> Endless invention, endless experiment,
> Brings knowledge of motion, but not of stillness".

But so long as we are to have change—and it seems inevitable—let us master it. T. S. Eliot goes on:

> "Where is the wisdom we have lost in knowledge ?
> Where is the knowledge we have lost in information ?"

My predecessors have spoken of the shortcomings of the active world—to me they are but the fallings short of science. Wherever we look we discover that if we are to avoid trouble we must take trouble—scientific trouble. The duality which puts science and man's other activity in contrasted categories with disharmony to be resolved, gaps to be bridged, is unreal. We are simply beholding ever-extending science too rough round the edges as it grows.

What we have learnt concerning the proper impact of science upon society in the past century is trifling, compared with what we have yet to discover and apply. We have spent much and long upon the science of matter, and the greater our success the greater must be our failure, unless we turn also at long last to an equal advance in the science of man.

Summaries of Addresses of Presidents of Sections[*]

Trends in Modern Physics

IN his presidential address to Section A (Mathematical and Physical Sciences), Prof. Allan Ferguson, after referring to the heavy loss which physical science has suffered in the deaths of Sir John McLennan, Sir Richard Glazebrook, Sir Joseph Petavel and Prof. Karl Pearson, discusses those remarkable changes of outlook which have characterized the development of physical science in the twentieth century. The evolution of molar mechanics along Newtonian lines; the extrapolation of the perceptual facts involved in the behaviour of macroscopic masses down to the dimensions of atomic magnitudes, and the success attendant on this extrapolation; the wave theory of light, which was so successful in co-ordinating old facts and predicting new ones as to draw from Lord Kelvin a noteworthy expression of his belief in the objective reality of the ether; these were outstanding contributions of nineteenth century thought to physical science.

Withal, there was considerable simplicity—not to say confusion—attendant on the definition of such a fundamental concept as that of mass.

With the closing years of the century, the discovery of the electron, of radioactivity, and the investigation of the manner of distribution of energy in the spectrum showed the existence of complexities and contradictions beyond the powers of the classical theory to explain or to resolve; and the last year of the nineteenth century saw the birth of those ideas which have given to our vocabulary a new verb—*to quantize*. The development is sketched of quantum notions as shown in the Rutherford-Bohr atomic model, the vector model of the atom, the dualism of outlook which emphasizes now the wave-aspect, now the particle aspect of matter and of radiation and the resolution of that dualism by the later developments of quantum mechanics.

Discussion of the new concepts introduced by the discoveries of the neutron and positron, and the positing of the neutrino to save conservation processes, leads to consideration in some detail of the development of the doctrine of causality and the definitions of *cause* given by Locke, Hume and Mill, the effect on the doctrine made by the enunciation of the uncertainty principle, and the attempt made by Planck to save the principle of causality.

Is it possible for the plain man of science to order his daily work on a rational basis without of necessity becoming a technical metaphysician? The work of Karl Pearson, amended and extended to meet modern demands, points the way to a possible solution—a solution which, indeed, has some affinities with the endeavour of Prof. Planck to rescue the principle of causality. If the distinction is kept clear between the conceptual model, and the perceptual facts which the model is invented in order to subsume; if it is realized that the world-model, be it built up of billiard-ball atoms or probability-smears, in Euclidean or some esoteric form of hyper-space, remains a model still, and that, until any part of the model emerges into the region of perception, talk of its reality is rather beside the mark; if the twentieth century man of science is as ready to discard a worn-out model as ever Maxwell was, he is not likely to steer wide of the mark.

The man of science of to-day is called upon, more insistently than at any other period of history, to remember that he is a social animal. He can no longer continue to offer sacrifices at the shrine of the Idol of Purity; he must be prepared to consider the social repercussions of his work, whether these repercussions be eugenic or dysgenic. Section A has already initiated the consideration of such implications—it is hoped that the officers of the Section will continue to emphasize and to widen this aspect of the Section's work.

Training the Chemist for Service to the Community

THE place of the chemist in the present-day community, and the manifold ways in which chemistry is involved in the solution of national and industrial problems, is the topic of the presidential address to Section B (Chemistry) by Prof. J. C. Philip. Any society which is intellectually alive will foster the spirit of inquiry, and the prosecution of research is perhaps the fundamental service which the chemist renders to the community. Mere accumulation of knowledge, however, which does not lead to action directly or indirectly is inadequate and unsatisfying, and it is because in the field of chemistry the academic search for new knowledge has led to such abundant practical achievement in the industry of the nation and the health of its citizens that the science deserves fuller recognition by the public.

---

[*] The Presidential Address, and addresses by the Sectional Presidents, are being published as "The Advancement of Science, 1936". (Blackpool: B.A. Reception Room. London: Burlington House.) Price 3*s*. 6*d*.

It is a commonplace that discoveries at first of a purely scientific character have frequently turned out to have unexpected applications, and it has become clear that, so far as research and discovery in pure chemistry are concerned, a very long view indeed must be taken in assessing their practical value. Further, it must not be forgotten that a solution of even the most ordinary chemical problems on rational lines is possible only because of our accumulated knowledge of natural phenomena and natural laws. Work, therefore, in the field of pure chemistry builds up a reserve of knowledge and technique on which future generations can draw in attacking practical questions.

It is with this background that so much 'directed' research is prosecuted at the present time—research, that is, which aims at the solution of some specific problem of industrial or national significance. During the last twenty years there has been a notable expansion in the amount of directed research, and in this movement the State has taken a prominent share. Apart from the initiation of industrial research associations, the State has itself organized research on certain chemical problems of national importance, such as those connected with the utilization of fuel, the preservation of food, and the pollution of rivers. Many of these questions require the collaboration of men of science other than chemists, and indeed some of the most fruitful scientific investigations are co-operative in character.

Apart from research, very many trained chemists —the general practitioners of the chemical profession—are engaged in work of a more routine, but highly important, character, and their contribution to the smooth running of industry and to healthy living is far greater than most people realize. A study, indeed, of the occupations of chemically trained men shows that, in the industry of the country, the chemist is ubiquitous. This suggests that those who picture him as concerned mainly with explosives and poison gas have an entirely wrong perspective. The use of chemical substances for destructive purposes is a prostitution of knowledge and skill which chemists would like to see eliminated.

The great variety of the tasks with which the chemical profession is concerned means that the training of the chemist at our universities and colleges must be on broad, fundamental lines. The day, however, has gone by when chemistry could be treated merely as a philosophical discipline; so far as the service of the community is concerned, it is a practical science. The universities must accept the burden, as they have already done in medicine and engineering, of putting the vocational training of chemists on a broad foundation of scientific knowledge.

Palæontology and Humanity

THE biological aspect of palæontology forms the topic of Prof. H. L. Hawkins's presidential address to Section C (Geology). The first part of the address is a re-statement of the basic facts about fossils, and is followed by an appraisement of their value in the attempt to decipher the history of life. Comparison of the records of palæontology and human history shows that fossils, for all their incompleteness, give on the whole a surer basis for historical reconstruction than documents or monuments. A corresponding comparison between the principles of taxonomy in palæontology and neontology shows inevitable differences that may lead to confusion if overlooked. Many of the characters of living organisms, rightly regarded as of specific value by neontologists, are quite inaccessible in fossil material; even when they seem to be recognizable, they cannot be proved to have a truly specific significance. In skeletal structures, differences that would justify taxonomic distinction between fossils can usually be matched with generic or even family differences in living organisms. Hence such terms as 'genus' or 'species' are used in different senses, and should be enclosed in inverted commas when applied to fossils.

Palæontology treats of the history of organic structures, not with that of the organisms themselves. Actually, this proves a distinction with very little difference, since organisms are dependent for their behaviour and welfare on the qualities of their component structures.

Analysis of the time-ranges of fossil groups leads to the conclusion that simplicity of structure, combined with reasonable efficiency, gives hope of longevity; while complexity of structure, in spite of its possibly greater efficiency, is relatively ephemeral. In the sphere of morphogeny, the meek inherit the earth and pride precedes a fall.

A review of the palæontological evidence of morphogeny shows 'orthogenesis' to be the prime factor in evolution, with environment acting as educator or executioner according to the plasticity of its victim. The impression gained may be summarized by stating that "the way life is lived is the way of evolution, whether it be from the Cambrian to the Holocene or from the cradle to the grave".

Mankind, viewed in palæontological perspective, appears in a dual role. He is a highly specialized member of a highly specialized class, and so seems doomed to a brief career. But his mental specialization seems to give him the all-round efficiency that is associated with generalization and its prospect of longevity. However, the historical record of human institutions has been, to date, an illustration of the transience of the complex—typical in all but its speed. Man, when he plays the animal, submits to the fate normal to animals, and his exaggerated capacity only accelerates his doom.

With the mental acumen that enables mankind to be a supreme animal, there has developed a faculty that is different and unique. This faculty, which may be called 'altruistic', seems in many ways independent of, and perhaps triumphant over, environment. To man, the clever animal, palæontology points, albeit despairingly, to the precipice just ahead; but to man, the idealist, it has no message, save to welcome a new experiment that may perchance succeed in justifying the nobility of his aspirations.

Natural Selection and Evolutionary Progress

THE subject of Prof. Julian S. Huxley's presidential address to Section D (Zoology) is the relationship of natural selection and evolution. On a Mendelian planet, such as ours appears to be, evolution is the joint product of mutation and natural selection. Recent work has altered our views as to the details of the process. The action of a particular gene depends on many other genes which act as modifiers; thus selection of the genic background is of great importance. By this means, deleterious effects of an otherwise advantageous mutation can be buffered or even abolished. Dominance and recessivity seem to be due to a similar action on recurrent mutations.

Analysis of this kind, however, only takes us a certain way. We must remember that evolution is a heterogeneous process, which will appear very differently to different groups of workers.

The origin of species is but one of the major problems of evolution: the others are the origin of adaptations and the origin and maintenance of long-range trends.

Species, it is now clear, can originate in several different ways. Their origin may be *unilinear*, when one species is wholly transformed into another; *divergent*, when one species diverges into two or more (as after geographical or physiological isolation); *convergent*, when a new species is formed by hybridization between two species (as in *Primula Kewensis*, *Spartina Townsendi*, etc.); or *reticulate*, when divergence and convergence combine to give a network of forms (as in roses, willows, and man). Furthermore, it may be either gradual or abrupt. The divergent origin of new forms after isolation appears always to be gradual, while their convergent origin (by allopolyploidy) after hybridization is always abrupt.

From the point of view of natural selection, speciation falls into two sharply distinct categories. When the characters distinguishing species arise abruptly, selection can have no part in deciding their nature: when they arise gradually, for example, after isolation, it can, and probably in large part does do so.

The origin of adaptations must be sought mainly in natural selection. Whenever an adaptation involves a number of steps or separate characters, no other agency but natural selection can have been operative. Thus, in the great majority of cases, pre-adaptation is ruled out. Natural selection is a mechanism by which results that otherwise would be in the highest degree improbable are rendered probable.

The origin and maintenance of long-range trends in all the numerous cases where the trend is towards functional specialization or improvement will be due to natural selection in the same measure as is the origin of adaptation. The directive character of such trends is no evidence of internally-determined orthogenesis, but is to be expected on a selectionist interpretation. Trends such as that of the elephants, in which the functional improvement is continuous, but the structural mechanism adopted is altered during the process, are incapable of orthogenetic explanation. A trend towards specialization will cease when certain biomechanical limits are reached to further advantageous advance.

Evolutionary progress may be defined as all-round advance in control over, and independence of, environment, while most long-range trends are one-sided specializations, and therefore blind alleys. Since it confers advantage, biological progress can equally be ascribed to natural selection.

Many evolutionary phenomena are better understood when it is realized that most genes act by controlling the rates of processes. In particular, many otherwise puzzling phenomena of recapitulation and anti-recapitulation at once become comprehensible. Anti-recapitulatory phenomena due to the slowing of early processes and the consequent removal of previous adult characters from the life-cycle are of great importance in evolution, accounting for neoteny, clandestine evolution, and fœtalization. This last process has been essential for the evolution of man: it is interesting that it could not have occurred in a polytocous form, where slowing of early growth would be prevented by intra-uterine selection.

An analysis of evolutionary progress reveals some interesting facts. In the first place, it appears that it could only have pursued the course that it has actually taken. Conceptual thought could only have arisen in a monotocous mammalian type with an arboreal ancestry. Non-arboreal and polytocous mammals are excluded; so are birds and other terrestrial vertebrates; so are insects and all other invertebrate groups. No further biological progress is now possible, except in man. Another feature of progress is that characters essential for one progressive advance may be a handicap for later progress. This must be taken into account in planning further progress—that is, in any eugenic scheme.

The Mapping of our African Colonies

THERE has been talk and correspondence lately on the backwardness of Ordnance Survey revision. Maps and Plans are not kept up-to-date and a great deal of inconvenience has been caused by this fact. It is becoming evident that town planning, building, road programmes and the like make up-to-date maps a necessity and not a luxury. It is not to be wondered at that similar problems have arisen in the African Colonies, the budgets of which have been just as hard hit as that of England. In his presidential address to Section E (Geography), Brigadier H. S. L. Winterbotham deals with this question.

The Ordnance Survey is strictly domestic. It has no duties outside the area for which our own parliamentary estimates are framed. The first step towards colonial mapping and surveying was taken in 1803, when the War Office formed the "Depôt of Military Knowledge" (maps were generally considered "military" in those days). In 1855 Lord Panmure, Secretary of State for War, arranged for a more energetic campaign, and he and the Secretary of State for the Colonies, working together, relied upon the same body, now called the "Topographical Department", to keep in touch with colonial survey departments and to intervene for their assistance, as often as possible. The colonial survey departments are concerned mainly with those property surveys which correspond to the large-scale plans of the Ordnance Survey, and the Topographical Department supplied officers and men for topographical mapping.

This dual arrangement has succeeded in providing a large area of good mapping, but it has failed in these post-War years to secure a proper and progressive programme of triangulation and mapping.

There is no question that comparatively enormous sums of money were squandered in England early in last century for lack of scientific forethought. The expenditure of two million pounds upon the unchecked and uncorrelated tithe maps is a case in point. The Grand Triangulation should, of course, have come first. In India the question was tackled sensibly and energetically in the correct sequence. In Africa the first essential is an arc of triangulation from Cape Town to Cairo, upon which all other surveys can be hung. Sir David Gill, H.M. Astronomer at the Cape early in this century, made a good beginning, and it was due to his personal foresight and vigour that this arc had reached the southern end of Tanganyika by 1914. Sir Charles Close added a portion in Uganda, and his whole-hearted co-operation as head of the "Geographical Section" (the new title of the Topographical Department) secured the skilled observers for the triangulation, and made it possible to map considerable areas at the same time. Before the Great War, more than 2,000 miles of the arc of triangulation had been finished. In exactly the same period (thirteen years), between 1922 and 1935, only 360 miles were added. In thirteen years before the War, 480,000 square miles were well mapped; in the thirteen years after, no more than 170,000 square miles.

The machinery exists, the problem grows more urgent in proportion as the development of local resources becomes more important. What seems to be lacking is the realization of the ultimate economy and wisdom of tackling the job in the proper sequence. Mapping and development are bound to go hand in hand.

Problems of Plantation Economy

IN his presidential address to Section F (Economics and Statistics), Dr. C. R. Fay, who has just returned from a visit to the East, discusses the problems of plantation economy with special reference to the tea industry. The evolution of the plantation can be traced from the early tobacco and sugar plantations of North America, through the indigo plantations of nineteenth century India to the tea and rubber plantations of to-day in India, Ceylon and Malaya; and tea can be compared as a commodity with tobacco, sugar, coffee, rubber and forest produce in order to show the scope and method of the plantation form.

The tea estate usually has upon it a tea factory; and thus plantation economy presents two classes of production problems: (*a*) cultural problems connected with the growing of the leaf; and (*b*) industrial problems connected with the processing of the leaf into tea. Growing embraces the clearance and planting of the land, the cultivation of the plant and conservation of the soil, the plucking of the leaf. Processing involves the factory sequence of withering, rolling and breaking, fermenting, firing, sifting and packing. In the main, plantations are financed and managed by

Europeans; and there are four types of plantation to-day: the proprietary planter (now rare), the small company, the large company and the consumer company. In the last class, the English and Scottish Joint Co-operative Wholesale Society, Ltd., is important. The 'optimum' size of the estate is increasing; and the productive unit is in process of integration along two lines: (*a*) the combination of estates into 'groups' and (*b*) the association of estates with coastal agency houses, which have functions of buying, selling, technical supervision and financial control.

The tea estate carries an important labour force, and its labour problems are threefold: recruitment, wages, health and housing. These vary according to the district, and the conditions in Assam, South India and Ceylon differ. Ceylon in 1934–35 was visited by a malaria epidemic, which attacked a large section of the tea area and created conditions of famine in villages adjacent to the estates. It was caused by a period of prolonged drought, and the measures by which it was fought are revealed in the official documents of 1935 and 1936.

Since 1933 South India and Ceylon have participated in the international scheme of tea export control. Regulation of export means restriction of production. It presents difficult problems, but it came in an industry which was already accustomed to joint action in other fields—in the regulation of labour, the provision of medical services and the undertaking of technical research, which in Ceylon is conducted at the St. Coombs Research Institute. In effect, the new control regulation is voluntary group effort, endorsed by the State. Tea control (1933) was followed by rubber control (1934), and both schemes are distinguished by the fact that, unlike the post-War rubber scheme, they include the Dutch East Indies.

The nature of regulation in plantation commodities can be compared with that in forest produce, where the problem of conservation is uppermost.

The Engineer and the Nation

IN his presidential address to Section G (Engineering), Prof. W. Cramp avoids technical matters, and confines himself to a review of the relationship between the engineer and the nation. The engineer shares with the devotee of pure science the detached pursuit of truth, but his work, like that of the doctor, is practical in its aspect, and entails not only daily contact with humanity, but also an understanding of human desires and of human psychology. This dual role gives him a greater opportunity both for the development and for the loss of character, but it also makes him more balanced and adaptable than his colleague in pure science.

Engineering at its best is the greatest instrument of civilization that the world has ever seen, because it is so largely concerned with the development of means of communication. Its natural tendency is to promote a closer contact between individuals and nations, but when deflected from this path of peace, it may equally become a terrible agent of destruction and death. For these reasons the activities of the engineer and the uses to which they are put are matters of supreme importance. To what extent does the nation recognize its responsibility towards the engineer, and how does the engineer respond ?

The attitude of the nation towards the engineer is reflected in the status, protection and remuneration that are accorded to him. A sharp contrast exists between his position and that of the medical man, whose period of training is only a little longer and whose responsibility is probably less. By means of his professional organization with statutory powers, the doctor has acquired a proper status with perhaps too much protection. At present the engineer has liability, without appropriate status, remuneration or protection.

The responsibilities of the engineer are emphasized by the charges brought against him by pulpit and press. Of these the first is the statement that engineers lend themselves too willingly to works of destruction. The answer is that pure science recognizes no moral distinctions, so that this is a matter of individual conscience in which the engineer is on a par with the rest of mankind The second is the suggestion that a moratorium should be imposed upon scientific development; to which the answer is that the invention of a machine does not compel its use. The third charge against the engineer is his lack of fertility in producing inventions which might lead to new industries. This is explained by the clumsy, costly and ineffective protection of patentees and by the absence of scientific representatives upon governing bodies in the State and in industry. In both directions reforms are needed.

The attitude of the engineer towards the nation involves professional conduct, both individual and collective. There have been engineers whose opportunities of acquiring a high standard of values were ideal, yet they surrendered integrity to self-interest when temptation arose. Among collective activities, mention may be made of the growth and development of trade associations; and of the dangers inseparable from powerful monopolies. The action of such groups in developing and maintaining a high standard of quality is gratefully acknowledged, but it is suggested that there is also some evidence of a tendency to exploit the nation for the benefit of a particular industry. This, if not checked, will react to the detriment of the associations themselves.

Conclusions drawn from the whole analysis suggest a number of reforms. These are : (1) The establishment of an engineering body with statutory powers to prevent unqualified persons from jeopardizing life and to check unprofessional conduct ; (2) the proper representation of science in State and municipal departments ; (3) a drastic revision of patent procedure in the law courts ; (4) voluntary renunciation by trade associations of any advantage unfair to the nation ; (5) an inquiry by educational experts into the best means of inculcating a higher scale of integrity among members of the profession. Of these reforms, it is suggested that the British Association might lend its aid in connexion with the second, third and fifth.

Cultures of the Upper Palæolithic

MISS D. A. E. GARROD deals in her presidential address to Section H (Anthropology) with the Upper Palæolithic in the light of recent discovery. The last twelve years have seen a new impetus given to prehistoric studies by the multiplication of researches outside Europe. This has led to a partial revision of the classification of Palæolithic cultures associated with the name of de Mortillet. In particular, it is becoming clear that the old division into Lower, Middle and Upper Palæolithic has a chronological value only, and that for purposes of typology the fundamental division is into hand-axe, flake and blade cultures.

In considering the present state of our knowledge of the blade cultures one point emerges clearly—the diversity of the strains which have hitherto been grouped together under the heading of Aurignacian. This is borne out by Peyrony's researches in the Dordogne and by recent work in the Near East, which lead to a distinction between the industries characterized by the blunted-back blade, formerly classified as Lower and Upper Aurignacian, and the Middle Aurignacian, in which the type-implements are steep and rostrate scrapers. Peyrony suggests that the first group should be labelled Perigordian, and that the old name of Aurignacian should be kept for the second.

A study of recent excavations, more especially in Russia, the Near East and North Africa, suggests that the problem is extremely complex, and a new system is tentatively put forward. The former Lower Aurignacian is named Chatelperronian, the Middle Aurignacian remains as Aurignacian proper, and the former Upper Aurignacian is divided into Lower and Upper Gravettian, corresponding to the La Gravette and Font-Robert levels respectively. The origins of the Chatelperronian can be traced back into the Lower Palæolithic, both in Palestine and East Africa, and it is suggested that its centre of origin lies somewhere in south-west Asia. It may have given rise to the Capsian, by way of the Kenya Aurignacian, and may also have passed northward to develop into the Gravettian, which is abundant in Russia. The Aurignacian proper, on the other hand, shows a remarkable development in the Near East, and the Iranian plateau is suggested as a possible centre of dispersion.

We thus have three major provinces for the blade-cultures : the Capsian in Kenya and Little Africa, and the Gravettian in north-west Asia and eastern Europe, both possibly derived from the earlier Chatelperronian, but cut off from each other by the great Aurignacian province of the Near East. From the Gravettian and Aurignacian centres migrations pour into central and western Europe, and cultures which in their homelands tend to remain distinct succeed and influence each other until at the extreme limit of their journey we get the classic French sequence. The industries which mark the extreme end of the Pleistocene, such as the Magdalenian, etc., appear to be local developments of one or other of these stocks, while the Solutrean is an intrusive element, of Hungarian origin.

Circulation of the Blood

THE control of the circulation of the blood, which is such an important problem in relation to surgical shock, forms the subject of the presidential address of Prof. R. J. S. McDowall to Section I (Physiology). Only a few years ago the subject consisted of a large amount of little-related data, but gradually this is being pieced together. For example, the well-known and dramatic fact that stimulation of the vagus nerve will slow up or even stop the heart, is now recognized as indicating part of a mechanism by which the normal heart at rest is constantly subjected to restraint, the release of which results in cardiac acceleration such as occurs in exercise.

The requirements of physical exercise probably give the best indication of most of the mechanisms of the circulation. In the active muscles a number of chemical and nervous mechanisms bring about a dilatation of blood-vessels locally. That the sympathetic vasodilators are in part responsible for the dilatation is a recent development. At the same time, largely as a result of psychical activity, blood-vessels are shut down in less active parts such as the alimentary canal and the skin. This has hitherto been considered to be due to the action of the vasoconstrictor nerves, but it is now shown that probably there is a reduction of the general vasodepressor reflexes which arise from the carotid sinus and the cardio-aortic region. The evidence rests on the fact that severance of the reflex arcs results in increased venous flow and cardiac output, while circumstances which reduce vagus activity also reduce the activity of the general vasodepressor reflexes. Thus just as the vagus may be looked upon as determining the range of cardiac activity, so the depressor reflexes determine the amount of blood available for the heart.

Hitherto, it has been considered that these two mechanisms are concerned primarily with the maintenance of a mean arterial pressure, but several facts suggest that in exercise the loss of their sustained activity is of more importance than their maintenance. These are their great variability in different animals and under different experimental conditions, the profound effect of loss of the vagus on efficiency in exercise and the fact that the arterial blood pressure rises in spite of these mechanisms.

The Patterns of Experience

THE controversies in which psychologists are now engaged are a sign of life and progress in the science, but an eclectic position is reasonable, provided that one maintains a point of view sufficiently unifying to avoid the danger of becoming a mere collector of odds and ends of fact and theory. Such a point of view appears to be afforded by the hypothesis of mental schemata, originally suggested by Sir Henry Head, and since advanced in other connexions by Prof. F. C. Bartlett and Mr. A. W. Wolters, who has chosen this topic for his presidential address to Section J (Psychology).

At the Norwich meeting of the British Association; Prof. E. Rubin demonstrated that there are predetermined 'ways of seeing', and that perception can be shaped by factors extrinsic to the material experienced. Under the influence of such factors, the mind actively patterns its experience, so informing the sensory material as to make the percept consistent with certain subjective principles. This implies that the patterns of experience are already latent in the subject's mind as he confronts the world. How they can so exist is partly explained by a consideration of the patterns of behaviour as exhibited in instincts and skills. The first necessity of every organism is to remain alive, and this task requires that it should master its environment and make it manageable. To this end it develops skills, which are qualities of the organism in virtue of which it is prepared to deal more adequately with situations of a particular kind, though prepared only in an outline, flexible manner. Such a preparation for reaction, dependent upon the integrated effects of previous experience, has been termed a *schema*, and it now appears that Rubin's 'ways of seeing' can be brought under the same conception. Thus perception, memory and conceptual thinking have been brought under common principles. They are reactions preliminary to further behaviour, and depend upon the existence of pre-formed schemata.

The same conception can be applied to problems of social psychology, for society is only actualized in its impact upon individual lives. Society becomes a psychological datum because it exists immanently in the minds of its members. A social group exists as such in virtue of conative tendencies developed by individuals in the course of accommodating their behaviour to each others', so that an observable group pattern is the product of the skill-characters, or behaviour schemata, of the constituent members. Often the schemata are not open to inspection or description, having been developed for other purposes. The difficulty of stating the principles underlying the English Common Law is psychologically explicable if it is considered that they are the ways of living together developed by a nation.

The subject-matter of psychology is taken to be the activities of the individual organism striving to maintain its full integrity. To obtain control of its universe it must organize the material of experience into patterns manageable by it. To this end it develops skills which we have termed schemata, and the system of a person's schemata embodies all his experience up to the present moment, and determines the direction and pattern of his future experiencing. Thus in outline the 'ways of seeing' and the 'ways of living' are reducible to a common psychological genus.

Uses of Fungi

IN his address to Section K (Botany), Mr. J. Ramsbottom deals with many of the ways in which fungi have proved useful to man.

Edible fungi have been known from the earliest times, but only three species have been successfully grown on a large scale—the common mushroom (*Psalliota campestris*) in Europe and America, shiitake (*Cortinellus Shiitake*) in Japan, and *Volvaria volvacea* in many parts of the tropics.

Wood infected with fungi is used for various purposes, the green wood of Tunbridge Ware being the best known—the colour being due to the mycelium of the discomycete, *Chlorosplenium aeruginosum*; 'brown oak', much valued by wood-workers, has recently been shown to be due to infection by the beef-steak fungus (*Fistulina hepatica*), and wood rotted by *Mucor racemosus* is used as cattle food (*palo podrido*) in Patagonia.

The lack of chlorophyll imposes upon fungi their peculiar physiology, which has many consequences important to man. Every nation has its fermented drinks or foods, mostly dating back to antiquity. Sometimes the fermentation is brought about by one or more yeasts, sometimes by a 'symbiotic' combination of yeast and bacteria. Many of the processes which were formerly left to chance are now controlled to a greater or less extent, and pure cultures of yeasts are employed. Similarly in cheese-making the appropriate species of the mould *Penicillium* is used for ripening blue-streaked cheeses (Stilton, etc.) and cream cheeses of the Camembert type.

While yeasts are the chief agents of fermentation in the West, Mucoraceæ and species of the *Aspergillus flavus-Oryzæ* group are mainly concerned in the East. The importance of *Aspergillus* in the preparation of soy sauce (the basis of many table sauces), saké and other products is shown by the estimated annual value to Japan as £40,000,000.

Recently there has been considerable development of the use of fungi in industry. Takadiastase produced by *Aspergillus Oryzæ* and its allies has many commercial uses as well as in medicine. Citric acid is now manufactured in many countries on a large scale by the action of dark-spored Aspergilli on sucrose, nine acres of mycelium being said to be held in commission by one American firm for use in cheese-making alone. Gluconic acid, now being used in increasing amounts as the calcium salt, which is more satisfactory for many purposes than is calcium lactate, is obtained on a commercial scale by the action of *Penicillium* species, for example, *P. chrysogenum* on commercial glucose.

During the Great War, Germany obtained her supplies of the glycerol necessary for the production of high explosives by trapping the intermediate products of sugar fermentation by yeasts; other countries developed similar methods. To supplement her inadequate bread ration, Germany employed *Torula utilis*, "mineral yeast", which is a poor fermenter but which grows readily on molasses, 100 gm. of this producing 130 gm. of yeast in eight hours. Russia also used a non-fermenting yeast, *Endomyces vernalis*, 'fat yeast', for food, the fat formed reaching 15–28 per cent of the dry weight in 10–15 days.

Many processes in which fungi play a part have been patented, and specifications cover the making of leather substitutes by tanning gelatinous growths, the artificial ageing of green coffee, the production of ergosterol, acetone, fumaric acid and so on. Substances which have not previously been obtained have been produced by the action of moulds, and it is evident that compounds of almost every type known to organic chemistry can be synthesized.

The Future in Education

If we consider that the goal of education is the making of men and citizens, that body, character and (in the widest sense) reason make the man, and need to be developed and trained, and that human beings cannot live intelligently in the world without some knowledge of literature, history and science, then we must admit that in spite of great achievements during the past sixty years in elementary, secondary, technical and university education, we have not produced an educated nation. We have provided opportunities for the minority who attend secondary school and university. Most of the rest have had no regular instruction after they leave school at fourteen years, an age when education in the real sense is about to begin, and this, according to Sir Richard Livingstone's presidential address to Section L (Education), is our great educational scandal and problem.

To solve it, two principles, commonly ignored, must be observed. First, it is useless to teach a subject before the mind can digest it. A liberal education cannot be given at the age of fourteen, fifteen or sixteen years. Secondly, the humanistic subjects—literature, history and philosophy—cannot be properly appreciated without some experience of life. In this they are unlike physical science and mathematics, which need no such experience. But if these principles are sound, our problem will not be solved by raising the school age to fifteen years; indeed, even an education which stops at the age of seventeen or eighteen is quite incomplete. Unless we are content to have a largely uneducated nation, we must establish part-time compulsory education to the age of eighteen years, and follow this up by adult education. Thus and thus only can we secure that the whole nation has a chance of being educated.

The great successes of adult education in England are the Workers' Educational Association and the university extension movement. The former provided for the working-class intelligentsia, but left the masses untouched. If we are to reach them, we must develop a different, less academic, technique in adult education. In particular, we need to study the intellectual digestion of the average man (which is different from that of the intelligentsia), and also to develop the social, corporate element in education. On these points we can learn from the Danish folk high-schools and from the women's institutes, both of which reach a class which our adult education has largely failed to touch.

The future lies with adult education. Without it the masses will remain uneducated. But it is also needed for the 'educated classes', and an attempt should be made at the universities to provide opportunities for regular study by professional men, civil servants, politicians and others, whose systematic study and thinking is apt to end when they take their degree. Summer schools, doctors' 'refresher' courses, etc., are rudimentary forms of such study, which have evolutionary possibilities.

Soil Science

THE advances which have been made in soil science in the twentieth century are discussed in his presidential address to Section M (Agriculture) by Prof. James Hendrick. At the beginning of this century, agricultural research was in a low state in Great Britain, where there was only one great research station, a private institution, Rothamsted. That has now been altered and, under the guidance of the Development Commission, a system of agricultural research stations has grown up covering all the leading branches of agricultural inquiry. The development of the system of agricultural education has led to increase and improvement of agricultural research.

In the great advance which has taken place in agricultural investigation, the fundamental subject of soil science has received much attention, especially since the Great War. A great part of the inspiration has come from foreign sources. In all parts of Britain the climate is temperate and humid with a rainfall distributed over all parts of the year, but in a great country like Russia the climate varies from arctic to sub-tropical and from humid to arid and desert. The Russians studied soil formation and classification from the point of view of climate, and showed how greatly the character of the soil depends upon climate. Cut off as the British were from Russia by linguistic, political and geographical barriers, nothing was learned of this until after the Great War. Though the British Empire extends through an even greater range of climatic conditions than Russia, little account was taken of the influence of climate on soil formation, and classification was based more on geology. A revolution has taken place in our views since the development of international soil congresses has established contact with the soil scientists of Russia and other countries, and attention is no longer confined to the comparatively narrow range of soils found in the British Isles.

Another field in which great advance has been made in recent times is in our knowledge of base exchange and soil acidity, and in the application of colloid chemistry to the study of the soil. Calcium carbonate has lost, to the exchangeable bases associated with the soil colloids, much of the high place it used to occupy in agricultural chemistry.

The two great classes of colloids found in the soil are the mineral colloids of the clay and the organic colloids of the humus. Much advance has been made in unravelling the structure of the clay colloids, but the exact nature and structure of the humus colloids is still obscure.

Another sphere in which great advances have been made during the present century is in the manufacture of, and trade in, fertilizers. In the case of nitrogenous fertilizers, this has amounted almost to a revolution.

Preservation of Native Floras

THE preservation of native floras with special reference to the British flora is the topic of Dr. A. B. Rendle's presidential address to the Conference of Delegates of Corresponding Societies. The preservation of native floras is of high importance from a scientific point of view. The cases of St. Helena and the Bermudas are examples of interesting natural floras that had been largely destroyed by man's action, especially by the destruction of the trees and the introduction of alien plants which had proved superior in competition with the natural flora. But efforts should be made to preserve what remains. It will be a reproach to us if the only material for study by future students of a flora is that found in herbaria.

Our British flora is worth preserving. We cannot regard it as merely a part of the west European flora that invaded Britain after the disappearance of the glacial ice before we were cut off by sea. There is evidence for the survival of fragments of the original flora in sheltered unglaciated spots during successive periods of glaciation, and various elements of special interest may be associated with special areas that presumably remained open. Intensive work on British genera and species indicates that there is still scope for investigations of taxonomic, distributional and ecologic interest. Apart from an æsthetic point of view, there is good reason for efforts to preserve our flora, even though it has already been much changed by the action of man and his crops and herds.

Various means to ensure conservation can be used. The Plant Conservation Board of the Council for the Preservation of Rural England, in particular, does important work. Three methods of promoting conservation are available: legislation, education and Nature reserves. The last was fully discussed by Sir David Prain in his address to the Conference at the York meeting of the British Association. Its value in the preservation of areas of special types of vegetation such as an alpine flora, that of a Yorkshire dale, or a fenland such as Wicken or Chippenham, or smaller special areas, is inestimable. But the Nature reserve will not preserve the flora of the countryside as a whole, and here we are concerned with legislation and education. The former is only the next best thing, but until the community is educated to leave for the enjoyment of all that which appeals to the individual, some form of legislation seems necessary. The Conservation Board has enlisted the help of local Councils throughout the country and their response has been encouraging. Posters appealing for the preservation of wild plants have been very widely distributed, and the by-law approved by the Home Office forbidding uprooting on land to which the public have right of access has been adopted and copies have been posted in prominent places. Lists of species demanding special protection in individual counties, on account of beauty or rarity, have been prepared and circulated.

Up to the present it has not been found possible to frame a by-law for the protection of wild plants growing on private property.

Plants may be studied as growing; uprooting is rarely necessary, and, if it is desirable, permission from the owner of the land may be obtained.

The introduction of our native species by planting or sowing in places in which they have never been known to grow wild is strongly to be deprecated. A natural harmony is disturbed and the introduced species may oust other species or even increase to become a nuisance. Introduction of alien plants in wild localities, and indiscriminate seed scattering are thoroughly reprehensible.

Education of the adult is difficult. He is not interested, but may be reached by appeals or occasional talks by the B.B.C. and by helpful articles and notes in the public Press. The botanical collector who wants rare species for his herbarium or for exchange purposes is even more difficult to convert. Education of the children, instilling a love and respect for our wild flowers, seems the most hopeful method. A pamphlet on "The Protection of Wild Flowers" has been widely distributed by the Conservation Board among school teachers. Every school should, where possible, have a garden in which the children are encouraged to grow wild plants from seed and note their development. Flora's League publishes an admirable booklet by Mr. T. A. Dymes with full instructions for growing wild plants from seed.

The active co-operation of everyone interested is necessary if the movement is to succeed.

PRINTED IN GREAT BRITAIN BY FISHER, KNIGHT AND CO, LTD, ST ALBANS

Dartford-Purfleet Tunnel

BELOW Blackwall tunnel, which is thirty-five miles from the mouth of the Thames estuary, there are no facilities for crossing the Thames either by bridge or tunnel. The construction has now been approved of a tunnel, which will be called the Dartford-Purfleet tunnel and will connect the Purfleet-Grays Road on the north side of the river with the Dartford Southern by-pass, and a connexion will then be made with the London-Folkestone and the London-Hastings roads. As a first step (*Roads and Road Construction*, September 1), a pilot tunnel will be constructed 900 yards in length and with an internal diameter of 12 feet. Two ventilating shafts with diameters of 18 feet will be constructed on the Kent and Essex banks of the river. They will be approximately 100 feet in depth. The pilot tunnel will cost £300,000 and will provide information as to the strata under the river at this place. This will be very helpful in connexion with the construction of the main tunnel. The tunnel will be rather more than a mile in length. The cost of the whole scheme is estimated to be about three million pounds, the pilot tunnel costing about a tenth of this. The Ministry of Transport, which will be directly responsible for carrying out the work, has made, in conjunction with the county councils of Essex and Kent, all the necessary arrangements. This tunnel, which will be twelve miles down the river from the Blackwall tunnel, will form a much-needed link between the north and south sides of the Thames Estuary.

Electrical Accidents in 1935

THE report on electrical accidents in 1935 by H.M. electrical inspector of factories (London: H.M. Stationery Office. 9*d*.) is of special value to all who design and operate electrical apparatus. The total number of accidents reported under the Acts was 447, of which 23 were fatal. Although the use of electricity has doubled during the last ten years, the annual total of the number of accidents has varied very little. The total number, twenty-three, of fatal accidents on factory premises is eight less than last year. This is probably due to the much larger use now made of artificial respiration when attempting to revive the victims of electric shock. In successful cases the time of application necessary varied from a few minutes to half an hour. Last year there were nine successful cases, but if it had been tried in every case there would doubtless have been more, as signs of life in some of the cases which ended fatally were evident after the shock. The inspectors specially mention the very rapid growth of electric arc welding to structures of all kinds. Although there were thirty-six electrical accidents to electrical welders, none of them was fatal. This is probably largely due to the attention now being paid to the personal equipment of the operator. Gauntlets, hand screens and helmets are made of suitable insulating materials, and are standardized. In addition, the harmful effects produced on the eyes of workmen not concerned in the welding processes, but liable to flashes from an arc in their vicinity, are considered. It has been found that plain glasses cut off a large proportion of the harmful ultra-violet rays. Until they had experienced the painful effects of eye flash, workmen were reluctant to wear them; in works where they are used, eye trouble has been eliminated.

New Conceptions of a Rock Garden

ENGLISH gardens have been enriched with many beautiful herbaceous plants from South Africa, but the succulent and xerophytic species of that region are not yet common in England. The rockery which is being made in Johannesburg for the Empire Exhibition of September, 1936–January, 1937 should provide an adequate portrayal of South Africa's wonderful endowments in these sections of its flora. Prof. John Phillips, professor of botany in the University of the Witwatersrand, describes the rockery in the *Journal of the Royal Horticultural Society* of August, 1936. It is planned upon a scale which is somewhat gigantic when judged from most English standards. Summits are broken with plantings of *Aloe Marlothii*, *A. dichotoma*, and other species, whilst the most striking effects are produced by the mesembryanthemums, the euphorbias, members of the genus *Encephalartos*, the pelargoniums, and by *Aster capensis*, *Dimorphotheca Ecklonis* and *Euryops athanasia*. A stream, rushing from the rock garden into the lake below, affords opportunity for the planting of indigenous hygrophilous plants, and lawns of *Cynodon* sp. and *Pennisetum clandestinum* have been laid. Large woody shrubs, and even small trees, such as *Chilianthus arboreus*, *Rhus lancea*, *Dombeya rotundifolia*, *Cussonia spicata*, *Tecomaria capensis*, *Plumbago capensis*, and other species, are employed for certain effects. Mr. Frank Frith, an expert on succulents, is supervising the making of the rockery.

Early Man in Colorado—Further Investigations

EARLY in June, Dr. Frank H. H. Roberts, jun., of the Smithsonian Institution, Washington, D.C., resumed excavations on the Lindenmeier site in northern Colorado for the third consecutive summer (see NATURE, Oct. 5, 1935, p. 535). While this habitation or camp site of Folsom man, the only known site of its kind and the only source of more than isolated specimens of the characteristic grooved stone Folsom point, has produced an abundance of evidence of the mode of life of Folsom man, hitherto no human skeletal remains have been found in association with this culture. Dr. Roberts's investigations during the coming season, therefore, will be devoted especially to the search for human skeletal remains. That early man was a contemporary of the extinct forms of bison found on the Lindenmeier site and dating possibly from the last stages of the Ice Age, is incontestable, as the tip end of a point was discovered in the foramen of the spinal column of a bison, of which a considerable portion of the skeleton was uncovered with the bones still articulated. A further matter of interest is that the palæontological evidence obtained by Dr. Roberts points to a climate somewhat warmer than that of the present day, some of the invertebrates represented by fossils being considerably north of their present range.

Bureau of Human Heredity

THE object of the Bureau of Human Heredity, which has recently been founded (see NATURE, **137**, 795; 1937), is collection on as wide a scale as possible of material dealing with human genetics. Later, the tasks of analysis of material and distribution of the information available will be added. It is affiliated to the International Human Heredity Committee, which ensures co-operation in all areas where research is proceeding. The Council would be grateful to receive all available material from institutions and individuals, furnishing well-authenticated data on the transmission of human traits whatever these may be. Pedigrees are particularly desired; twin studies and statistical researches are also relevant. Announcements in regard to the services undertaken by the Bureau will be published from time to time. The address of the Bureau is 115 Gower Street, London, W.C.1.

Announcements

DR. H. R. MILL has been elected a member of the German Academy of Naturalists at Halle "in recognition of his original contributions to geographical science and particularly to Oceanography and the furtherance of Polar research". This Academy, the full title of which is the Kaiserlich Leopoldinisch-Carolinisch Deutsche Akademie der Naturforscher, was founded at Schweinfurth in 1652 by a group of medical men who called themselves the Argonauts, as their object was to explore new realms of science in order to bring back the 'gold of knowledge' for the benefit of mankind, an aim which it now defines as the study of Nature for the good of humanity.

MR. R. A. WATSON WATT has been appointed superintendent of the Air Ministry Research Station, Bawdsey Manor, Suffolk. Mr. Watson Watt began his Civil Service career in the Meteorological Office, and later was appointed superintendent of the Radio Research Stations of the Department of Scientific and Industrial Research at Aldershot and Slough. He became superintendent of the Radio Department of the National Physical Laboratory when it was formed in 1933. In this post he has been responsible for an increasing amount of important work for the Air Ministry, especially in connexion with radio direction finders and beacons. His present appointment arises from a decision by that Department to establish a research station to continue this work.

PROF. FRANZ FISCHER, of the Kaiser-Wilhelm Institute, Mulheim-Ruhr, will deliver the Melchett Lecture of the Institute of Fuel at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1, on October 15, at 3.30 p.m. The subject of Prof. Fischer's lecture will be "Production of Synthetic Motor Spirit".

THE Prussian Academy of Sciences has awarded the gold Leibniz medal to Prof. Heinrich Lotz, of Berlin, and the silver Leibniz medal to Dr. Ludwig Kohl-Larsen, of Allensbach a. Bodensee.

PROF. REINHOLD RIECKE, director of the Chemico-Technical Experimental Institute of the German Porcelain Factory of Berlin and scientific director of the German Ceramic Society, has been nominated an honorary member of the American Ceramic Society.

IN connexion with the research item in NATURE of July 11, p. 83, on the Netherland's Meteorological Institute's publication, "Oceanographic and Meteorological Observations in the China Seas", Mr. H. Keyser, of De Bilt, writes that for the English text very valuable assistance was given by Mr. E. W. Barlow, of the Marine Division of the Meteorological Office in London, who took much trouble in correcting the manuscript, etc. Mr. Barlow has also given assistance, "on behalf of international co-operation", in the preparation of Part 2 of the work.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

An inspector of agriculture in the Department of Agriculture and Forests, Sudan Government—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, London, S.W.1 (September 15).

Two junior investigators for the Royal Commission on Historical Monuments—The Secretary, 29 Abingdon Street, London, S.W.1 (September 19).

An assistant horticultural instructor for the Hampshire County Council—The Clerk, The Castle, Winchester (September 21).

An assistant lecturer in electrical engineering in University College, London—The Secretary (September 23).

An instructor in engineering workshop practice and production engineering in the Borough Polytechnic, London, S.E.1—The Principal (September 23).

A head of the Production, Engineering and Trades Course Section of the Department of Mechanical Engineering, and a lecturer in metallurgy, in the Central Technical College, Birmingham—The Chief Education Officer (September 26).

An assistant conservator of forests in the Department of Agriculture and Forests, Sudan Government—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, London, S.W.1 (September 30).

A biologist for research in the eastern Canadian lobster fishery—The Director, Atlantic Biological Station, St. Andrews, N.B., Canada.

A temporary assistant engineer in the Experimental Section of the Ministry of Transport—The Establishment Officer, Ministry of Transport, Whitehall Gardens, London, S.W.1.

Architectural and structural engineering assistants in the Design Branch of the Directorate of Fortifications and Works at the War Office—The Under-Secretary of State (C. 5), The War Office, London, S.W.1 (quote 8314).

An assistant master to teach zoology in the Swansea Technical College—The Director of Education, Education Offices, Guildhall, Swansea.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 469.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Conservation of Energy in Radiation Processes

AT the beginning of this year, R. Shankland[1] reported experiments on the Compton effect which, indicated a breakdown of the conservation laws in radiation processes and a reversal to the type of theory put forward by Bohr, Kramers and Slater in 1924. According to the latter, light-quanta have no existence, and energy is only statistically conserved in the interaction of matter and radiation. In view of the difficulties of accepting Shankland's results—it was pointed out by one of the present writers in an earlier note[2] that they "run counter to the Uncertainty Principle"—we have carried out certain experiments with a view of testing further the points at issue.

In these experiments, which were referred to in the above-mentioned note, a narrow beam of X-rays ($h\nu \sim 20{,}000$ volts) is passed through a Wilson chamber containing argon, thus producing photo-electrons. Of the photo-electrons which come from the K-level, the great majority are accompanied by Auger electrons, the latter being produced by the process of internal conversion (the combination of the two tracks will be called a P track and represented in Fig. 1 by $/\!\!\wedge$). The remainder of the k-photo-electrons—about 1 in 13—are not accompanied by Auger electrons (Q_1 tracks, denoted /). On the light-quantum theory, and strict conservation, the ionized atoms which do not give Auger electrons emit a k fluorescent quantum, which, if absorbed in the surrounding gas, produces a photo-electron (F track, denoted $\backslash$). This state of affairs is represented in Fig. 1, the dotted line being the path of the light-quantum.

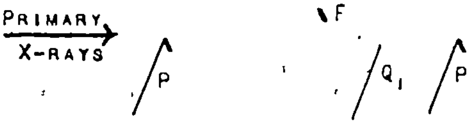

FIG. 1.

Now the ionized atoms have *exactly the same durations in the excited state* whether they give rise to an Auger electron or not, and on the theory of statistical conservation such as the Bohr-Kramers-Slater theory, they 'emit' fluorescent radiation to exactly the same extent, and *are equally responsible for the production of the fluorescent F tracks*. The latter would therefore not be associated with a Q_1 track any more than with a P track, while if there is strict conservation an F track has nothing to do with a P track. A test of the points at issue may therefore be made by seeing whether a track of the Q type is systematically associated with a fluorescent track or not. A statistical examination is necessary, especially in view of the fact that the photo-electrons coming from the L level (Q_2 tracks) are not distinguishable in the photographs from the Q_1 tracks, and are about equal in number.

Out of about 350 photographs (about 10 tracks per photograph, effective length of chamber $\sim$ 14 cm.) 21 were found with F tracks within 2 cm. of the primary X-ray pencil, in approximate accordance with the value of the absorption coefficient of argon for argon k-radiation, the argon being at a pressure of about 14 cm. A general inspection of the photographs showed a distinct association of Q and F tracks, indicating strict conservation. One of the photographs is reproduced above (Fig. 2), the short track by itself being that of a fluorescent photo-electron (F track) and the middle long track that of a primary photo-electron without an Auger electron (Q track).

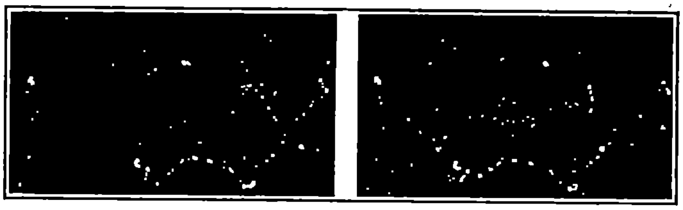

FIG. 2

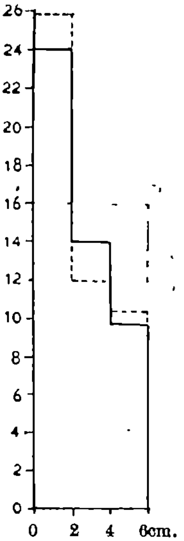

FIG. 3.

The distribution of the distances (x), measured parallel to the X-ray pencil, of the Q tracks from the F tracks for all the photographs is shown by the full line in Fig. 3, for x up to 6 cm. The calculated distribution according to strict conservation is represented by the broken line (– – –). The peak for small x represents the association of Q_1 and F tracks. The background is to be attributed mainly to the photo-electrons from the L-level (Q_2 tracks). The statistical fluctuation comes almost entirely from this background and is about $\pm 1\frac{1}{2}$. The total number of tracks per photograph is such that on the statistical theory the Q tracks have practically a random distribution with respect to the fluorescent photo-electrons. This is represented by the dotted line (......). The observed distribution is seen to have a peak in good agreement with the calculated distribution assuming strict conservation.

In view of Shankland's results, other workers have also recently carried out experiments on the conservation of energy and momentum in radiation processes[3]. In these investigations the counter coincidence method has been used. In all cases the results obtained, in conformity with the present results, confirm the light-quantum theory and the strict applicability of the conservation principles.

Influence of Temperature on the 'Groups' of Slow Neutrons

WE have investigated the influence of temperature on the activation of silver by slow neutrons, separating the effects due to the groups *A*, *B* and *C* as defined by Amaldi and Fermi[1]. The arrangement used is shown in plan in Fig. 1. Absorbers of cadmium (0·258 gm./cm.^{2}) and silver (0·077 gm./cm.^{2}) were employed to separate the groups, and the use of a thicker absorber of silver (1·023 gm./cm.^{2}) enabled changes in the absorption coefficients of groups *B* and *C* in silver to be measured. For the low temperatures the paraffin wax was cooled with liquid nitrogen or hydrogen. The results obtained were as follows:

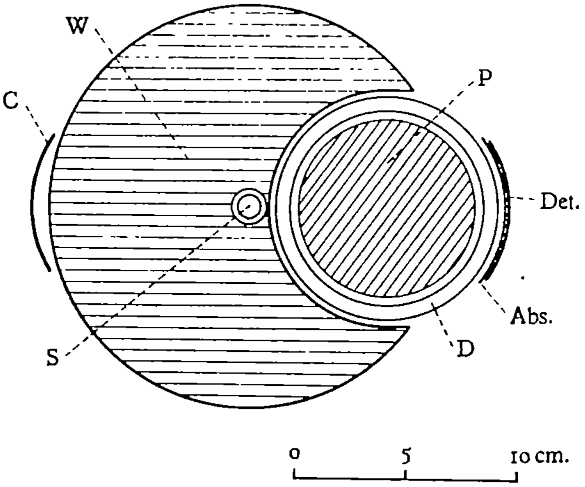

FIG. 1 *S*, neutron source (beryllium and radon); *W*, tin containing water; *D*, Dewar vessel; *P*, paraffin wax; *Det*, silver detector; *Abs.*, cadmium and/or silver absorbers; *C*, position of detector for comparison runs.

	Group	290° K.	77° K.	20° K.
Activity induced	*C* *B* *A*	100·0 ± 1 4 100·0 ± 2·0 100·0 ± 5·0	83·7 ± 1·3 101 4 ± 2·0 75·3 ± 5·6	96·4 ± 1 2 88·5 ± 1 6 72·0 ± 5·4
Absorption coefficient	*C* *B*	100 0 ± 4 5 100·0 ± 7 0	117·8 ± 5·2 123 1 ± 7 0	160·8 ± 5·0 110·6 ± 6 7
'Number of neutrons' $\left(=\frac{\text{activation}}{\text{abs. coeff.}}\right)$	*C* *B*	100·0 ± 4 7 100·0 ± 7 3	71·1 ± 3·2 82·4 ± 5 0	60 0 ± 2·2 80 1 ± 5·1

N.B. Each row has been scaled to make the first figure 100, and figures in different rows are not comparable. The errors shown are the mean square errors due to statistical fluctuations.

Some measurements using ice instead of paraffin wax in the Dewar vessel have given similar results.

It will be seen that groups *A* and *B*, as well as *C*, are affected by changes of temperature. This is in contradiction with the estimates of the energies of the former groups hitherto accepted[2], which gave values of several electron-volts, compared with the 0·037 e.v. or less corresponding to the temperatures used. For other reasons it appears unlikely that the energies of groups *A* and *B* have values lying in the region of thermal equilibrium, but according to our experiments they cannot be greatly in excess of such values. It follows from this that the assumption that the absorption coefficient of boron varies inversely as the velocity of the neutrons must be in error.

We desire to thank Lord Rutherford for putting the facilities of the laboratory at our disposal, and Dr. M. L. Oliphant for helpful discussions. It is hoped to continue experiments on these lines, and a fuller account will be published in due course.

Mechanism of Carbohydrate Breakdown in Early Embryonic Development

DURING the past twelve months, we have been engaged in a systematic study of the intermediary mechanisms of carbohydrate breakdown in the chick embryo in the first week of its developmental period. Although we have not yet brought our work to a conclusion, we wish to give an interim summary of it.

Attention has been concentrated throughout on the embryo of 4–6 days' incubation, and the first experiments done were measurements of anaerobic glycolysis with different substrates. It is found that glucose and mannose are the only sugars which give a steady long-continuing glycolysis; disaccharides, even when phosphorylated (such as trehalose-phosphate), and pentoses, are unattacked; as also is fructose. Chemical estimations show that lactic acid is formed quantitatively during glycolysis. Various parts of the embryo separately give the same result as the whole embryo, so that the relatively large proportion of nervous tissue present cannot be held accountable. Addition of inorganic phosphate does not increase the glycolytic rate of glucose or mannose, or cause the breakdown of other sugars. Glycogen is not glycolysed by pulped or minced embryo any more than it is by intact embryos, and even fairly active acetone powders prepared according to the method applied to brain by v. Euler, Gunther and Vestlin[1], will not glycolyse glycogen. With intact embryos, embryo-*Brei* and acetone powders, there is often an induction period of a few minutes in the glycolysis of mannose and glucose; this initial lag may be abolished by the addition of co-zymase or adenyl-pyrophosphate.

The trisaccharide of Levene and Mori[2] (2 mannose plus 1 glucosamine), contained in egg proteins, is not attacked by intact embryos; but when the mannose has been made available by hydrolysis, embryos can glycolyse the product. Probably the yolk-sac hydrolyses it *in vivo*. Glucosamine itself is not glycolysable, and another trisaccharide, raffinose, is also unattacked.

Chick embryo resembles mammalian brain in that its glycolysis, whether of glucose or mannose, can be almost completely abolished by the addition of glyceraldehyde. The autoglycolysis, however, cannot be inhibited in this way.

Study was also made of the appearance of bisulphite-binding compounds during embryonic glycolysis. By the methods of Clift and Cook[3], it was found that a considerable accumulation of pyruvic acid occurs both ærobically and anærobically. Of the carbohydrate glycolysed, some 60 per cent appears temporarily in the form of pyruvic acid, if no substrate is given, but if glucose is present the relative amount is much reduced (to less than 10 per cent) although more pyruvic acid appears. The accumulation of pyruvic acid occurs in embryo tissues of 10 days incubation also. In view of the work of Peters and his collaborators[4], on avitaminous bird brain, it was conjectured that the embryo might be physiologically B_1-deficient, but on the contrary the addition of crystalline vitamin B_1 had no effect on the pyruvic acid accumulations.

Next, the rates of anærobic and ærobic glycolysis of the embryo were compared with the rate of oxidative disappearance of lactic acid. In embryo, the Pasteur effect is extremely marked. If Meyerhof's resynthesis theory were the correct explanation of this, the rate of disappearance of added lactate (in the absence of glycolysable substrate) should be equal to the observed difference between ærobic and anærobic glycolysis in the presence of glucose. But in fact it is far less than that. Some explanation of the Pasteur effect in embryo, other than the Meyerhof cycle, must therefore be found.

In this respect, chick embryo resembles mammalian brain (Dixon[5]). The effect of potassium in increasing respiration and anærobic glycolysis observed by Ashford and Dixon[6] was, however, looked for, and found not to exist in the case of embryo. In this respect, it differs from brain.

Another line of attack which we have used is that of analysing the distribution of phosphorus among the various fractions of the aqueous trichloracetic acid extract. Chick embryo differs widely from muscle or brain in that no less than 60 per cent of its water-soluble phosphorus is found in the 'hexosemonophosphate' fraction unprecipitable with barium. This phosphorus-containing material cannot be the Robison ester and is probably not hexose-monophosphate at all, since it is not fermentable by yeast and contains too little phosphorus in the elementary analysis. It is very resistant to acid hydrolysis. Embryo is therefore similar to tumour, where, as Outhouse[7] has shown, a large amount of the same fraction is present, perhaps as hexosamine-phosphate or amino-ethyl-alcohol-phosphate; and with blood where, according to Kerr and Daoud[8], half the whole amount of phosphorus may be in the form of diphosphoglyceric acid.

The distribution of the phosphorus was further investigated after treatment of the embryos at 37° for some time with fluoride in a dosage just sufficient to inhibit glycolysis 90 per cent. The medium contained inorganic phosphate. Contrary to what would be expected if the embryo followed the example of muscle, there was no accumulation of difficultly hydrolysable esters; on the contrary, there was a piling up of inorganic phosphate at the expense of the phosphagen and the adenyl-pyrophosphate. This is not a specific effect of the fluoride, but happens also when the embryos are suspended in Ringer-bicarbonate anærobically without the addition of any substance. Upon the fraction not precipitable by barium, fluoride has no effect; this remains constant. It persists, moreover, in about the same relative proportion until at least the fifteenth day of development.

One of the main points of interest in this work is, of course, the question whether the embryo's carbohydrate breakdown is entirely, partially, or not at all effected by means of a phosphorylation system. At present we only wish to record that apparently neither intact embryo nor embryo-*Brei* will glycolyse any combination of the phosphorus-containing intermediates, for example, sodium glycerophosphate with sodium pyruvate, sodium phospho-pyruvate, or sodium phospho-glycerate. Dihydroxyacetone is not broken down, whether inorganic phosphate is present or not. As we expected from the work of Neuberg, Kobel and Laser[9], methyl-glyoxal is converted to lactic acid at a rate about half that of glucose, which under certain conditions may be increased by added sulphydryl. The embryo will not form lactic acid from hexose-diphosphate, glucose-monophosphate, or mannose-monophosphate. But on the other hand, inactivated embryo-*Brei* forms a dihydroxyacetone-phosphate fraction from added hexose-diphosphate to the same extent as mammalian muscle extract, and forms phospho-glyceric acid from phospho-pyruvic acid. It also transfers phosphorus from phospho-pyruvic acid to adenylic acid (the first part of the Parnas reaction). We hope that our experiments will shortly permit of final decision regarding the question of phosphorylation in the embryo.

Reliability of Seismograph Stations

IN a recent paper, Dr. H. Jeffreys[1] works out a 'reliability' factor for seismograph stations throughout the world, using information from the International Seismological Summary for 1930 January to 1931 March. Reliability results based on this information do not, however, represent present conditions. Seismology has made rapid headway since 1931, and a number of stations have improved both their recording equipment and their timing.

The characteristic which Jeffreys terms 'reliability' is obtained by expressing the number of P residuals not exceeding ±4 seconds, as a decimal of the total number of P residuals; so that the 'reliability' values vary between 0·0 and 1·0. A table of such values for each station is given, the stations being grouped into five regions. Of the seventeen stations in the 'Pacific' group, we find Wellington, with readings from two Milne-Shaw seismographs, taking thirteenth place; and Christchurch, with readings from a single Milne seismograph, taking fifth place. The 'reliability' values given are as follows :

$$\text{Wellington} \quad \frac{8}{24}=0\cdot3\,;$$

$$\text{Christchurch} \quad \frac{4}{8}=0\cdot5.$$

This surprising result led me to make a detailed examination of the data for Wellington and Christchurch. Working on the same lines as Jeffreys, and using the same data, I obtained the following values for the 'reliability' :

$$\text{Wellington} \quad \frac{11}{27}=0\cdot4\,;$$

$$\text{Christchurch} \quad \frac{3}{9}=0\cdot3.$$

The above results differ from those obtained by Jeffreys, but they are more in accordance with the instrumental equipment at the two stations. However, if more recent observations were used, both stations would undoubtedly have higher values.

The P residuals at Wellington are nearly all negative. Of the eleven not exceeding ±4 seconds, eight are negative, two are zero, and one is positive ; giving a mean residual of nearly -2 seconds. This suggests that the deviations found for this station are not random errors, and that the station should be classed with those showing systematic errors. These observations giving negative residuals refer to Pacific earthquakes with epicentres to north or north-west of Wellington, and it is possible that these need some readjustment, as there is generally a lack of near stations in eastern azimuths as compared with western azimuths. It seems certain, as suggested by Jeffreys, that sufficient weight has not been given to Wellington and Christchurch in the determination of Pacific epicentres.

In dealing with the utility of his results, Jeffreys selects a number of stations of good 'reliability' for each of the five regions. As 'Pacific' stations, those selected are : Riverview, Palau, Manila, with Melbourne and Adelaide to check Riverview.

This cannot be considered a complete list for years following 1931, since both Wellington and Christchurch would almost certainly be included as stations of good 'reliability'. Also, the standard errors of P should now be less than the value of 4 seconds, which Jeffreys applies to these stations.

R. C. HAYES.

[1] "A Comparison of Seismological Stations", *Mon. Not. Roy Ast. Soc., Geophys Suppl*, 3, No. 9, 423 (April, 1936).

I SHOULD agree with Mr. Hayes that not much importance should be attached to the difference between Wellington and Christchurch. The standard error of a reliability r based on n observations is $\sqrt{\{r(1-r)/n\}}$; then with my data the results are Wellington $0\cdot33\pm0\cdot10$, Christchurch $0\cdot50\pm0\cdot18$. This is for all earthquakes recorded at the stations. For Pacific earthquakes alone, I get Wellington $0\cdot36\pm0\cdot13$, Christchurch $0\cdot56\pm0\cdot19$. The difference is therefore not more than might be attributed to random sampling. On the other hand, we may notice that there were three times as many readings of P at Wellington as at Christchurch, though in most cases the amplitude of the motion of the ground must have been about the same, and many of the inferior observations at Wellington refer to earthquakes when Christchurch failed to record P at all.

The data as presented in the International Seismological Summary do not indicate the clearness of the movement, and it is probable that the clearer movements at Wellington correspond to a much higher reliability. I also directed attention in my paper to the fact that in some cases too little weight seems to have been given to the near stations in determining the epicentres, and that for this reason the reliabilities found for both stations may be too low for earthquakes in the South Pacific ; but to remove this error would mean recalculating the whole of the epicentres.

Support can be found for the higher reliability of Wellington in strong or fairly near earthquakes from the residuals at the British stations with Milne-Shaw instruments in the series of deep-focus earthquakes that I have discussed recently[1]. Oxford is excluded because it has already been found to have a high reliability. The residuals for the others together have the following distribution :

Residual (seconds)	−2	−1	0	1	2	3	4	5	6	7	8
Number	2	2	6	2	2	1	0	1	1	0	1.

These correspond to a mean reliability of $15/18=0\cdot83\pm0\cdot09$; but the mean for these stations for general work was only $0\cdot50\pm0\cdot08$.

The results in my paper do not place the stations in a definite order of merit, since the sampling error is appreciable ; but they serve to indicate approximate weights to use in the determination of epicentres. I should recommend using for Wellington, when within 30°, the weights for reliability $0\cdot6$ until further information is available.

"A Treatment of Modern Physics"

UNDER the above title, E. N. da C. A., in NATURE of June 13, has subjected my co-worker, Mr. N. K. Saha and myself, to a vigorous 'strafing' for writing "A Treatise on Modern Physics", Vol. 1, published by the Indian Press of Calcutta and Allahabad. In fairness to the large number of readers (not merely Indian) who, between the publication of the book in November, 1934, and its review in NATURE, have wasted, according to the reviewer, thirty shillings on a book advocating a "method of teaching" which he holds "to be pernicious", I, as the senior author, seek permission to publish the following apologia in NATURE.

Reviewers have their own right, which I do not propose to question, but they are expected to give a short *résumé* of the subject matter of the book, point out mistakes or misstatements of facts, find out possible errors in the presentation of current ideas and to deal with important omissions, as has been done in NATURE by Prof. R. H. Fowler in a review of another work by me. In no case have we come across a review in which the reviewer finds faults with the author for not including matter which is expressly stated to be reserved for subsequent treatment.

In the present case, the reviewer has followed an original line in his review. He does not give a *résumé*, does not point out a single mistake, and does not say that the presentation of ideas has been marked by any serious error or bad style. He deals only with *omissions*, in spite of the fact that the authors themselves noted these omissions in the following passage which occurs in the preface:

"It was first intended to include chapters on Molecular Physics, interaction between matter and light, wave-mechanics and Nuclear Physics, but as the book has already become bulky, it was decided to incorporate these chapters in a second volume."

Most of the omissions to which the reviewer devotes three-quarters of his criticism, namely, failure to give an account of the correspondence principles, selection rules, principles of wave-mechanics and also some advances on positive rays fall under the chapters mentioned above. The reviewer's remarks regarding the omissions are, therefore, not only irrelevant but also extremely ungracious to the authors.

As to the other minor charges—omission in Chapter iii (Positive Rays) of mention of Aston's and Bainbridge's precision mass-spectrograph and of the results obtained therefrom—the explanation is very simple. The present volume, being confined solely to discussion of atomic structure, the authors were justified in omitting all references to such works, which have a bearing on nuclear physics. This has been expressly mentioned on page 99. Further, at the time of writing, Aston and others (Rutherford, Oliphant, Kempton, Bethe) were engaged in revising the mass-scale. The authors did not, therefore, feel justified in including such matter as would become obsolete before the ink had dried. Probably if the results had been included, the reviewer would have found fault for their inclusion.

Regarding the chapter on magnetism, the authors were aware of the current theories of ferromagnetism, but on perusal of these had come to the conclusion that these theories were only 'phenomenological' and had better be omitted from a text-book. The wisdom of such a step was justified in Simon's recent discovery that, near the absolute zero, all paramagnetic substances tend to become ferromagnetic. This probably necessitates a revision of the current theories of ferromagnetism, which trace it to exchange resonance amongst the *d*-electrons of the transitional elements of the first group. I do not think that such matter as magneto-caloric effect or of magnetostriction need be incorporated in a book dealing mainly with atoms. It is possible to have legitimate differences of opinion on this question.

The reviewer complains that there has been too much of complex spectra in this treatise. In this connexion the following passage in his well-known text-book published in 1927 ("The Structure of the Atom") may be quoted:

"A discussion at Danzig in September, 1925, between some of the most celebrated workers in the field of quantum analysis of spectra, at which the writer had the pleasure of being present, foundered, if the expression may be used, on the question of notation, none of the speakers being able to understand the notation of the others and each having also apparently difficulties with his own."—(Footnote, p. 569.)

In spite of this situation nine years ago, the writer of this text-book, who according to his own admission did not at the time understand the subject, devoted 79 pages of his text-book to multiplet structure. The reviewer admits that the difficulties of a lucid exposition of the subject of complex spectra have largely disappeared as a result of advance of knowledge within the last ten years, but he puts forward the very curious view that the necessity of giving a full exposition of the subject, in the circumstances, no longer remains.

It is rather difficult to understand the reviewer's remarks about the inner quantum number and the spinning electrons. The writer's point of view has been the approach of the subject from the side of spectroscopy, while the reviewer would like to develop it from the mechanical side. The two views being divergent, the criticisms are rather ungracious. In one case he has misrepresented the actual language used about the rotating electron. I may add that Goudsmit and Uhlenbeck used the term "Rotierende Elektron". He writes "the perephral velocity is even worked out on these lines and the absurd value which results is said to be unexplained". The mathematical results, for quoting which fault is found, have been taken from Goudsmit and Uhlenbeck's original note to *Die Naturwissenschaften*, and the words used by these authors are as follows: "The linear velocity at the periphery of the electron thus comes out to about 308 times the velocity of light, a deduction which has still to remain *incomprehensible*."

The authors at any rate may be expected to know the methods of teaching, pernicious or otherwise, which prevail in India, and they do not propose to bother about the *ex cathedra* remarks of the reviewer on this question.

M. N. SAHA.

IT is now more years than I care to think of since books were entrusted to me for review in NATURE, but it is the first time that I have seen a letter anything like that which Prof. Saha has sent for publication, and in the original and longer form in which the Editor showed it to me it was even more individual. I can scarcely be expected, at this time of day, to take lessons from Prof. Saha as to how to review a book, or to deal with his letter point by point, especially as a great deal of it is, to speak mildly, disingenuous. I may remark, however, that it is not correct to say that I did not point out a single mistake, and, further, that I was less concerned with details than with general principles. It was owing to a delicacy which I now realize to have been misplaced that I did not remark on the style in which the book is set down. Perhaps Prof. Saha's letter furnishes comment on that point.

My criticism was mainly directed to the fact that the book contains masses of detail, much of it unnecessary and some of it out of date, omits matters of prime importance for the subject under discussion, and provides little or no explanation of the principles on which the complicated calculations printed in the book are based. I have made my point of view perfectly clear, as I am entitled to do, and have not misrepresented that of the authors, and, in my experience, misrepresentation and ambiguity are the sole grounds which are held to justify a reply to a review. Those who hold that the points raised are trivial will set me down as mistaken, as in the case of the spinning electron, where all the relevant matter is before the reader.

What I gather to be the point of Prof. Saha's present communication is, first, that all the missing matter which one might have expected to find in this book—

some description of the method of anode rays and of the work of Bainbridge in the chapter headed "Positive Rays"; some explanation of the general methods of quantization before, for example, fourteen pages are devoted to the calculations on the Stark effect; some mention of the work of Hartree and others where the old work on electron distribution is discussed; and, in short, all the other fundamental points which, as I point out in my review, are completely neglected—is going to be described in a second volume; and secondly, that I ought to have known this from the passage which he quotes from the preface. The answer is, first, that the passage which he quotes does not say this, and, secondly, that even if it did, this is, *in my opinion*, a bad way of writing a book, especially as Prof. Saha's disciples are still awaiting the second volume which shall explain the first. In my opinion—but Prof. Saha says that my opinion is not worth much. For all I know he may be right, but there his quarrel is with the Editor, who invited me to give it, and not with me. In any event, Prof. Saha's remark that the authors "do not propose to bother about the *ex cathedra* remarks of the reviewer" on methods of teaching absolves me from the distasteful task of spending further time on Prof. Saha's favourable review of this volume of his book. I look forward, however, to reading his review of the second volume.

E. N. DA C. ANDRADE.

'Lines' on the Surface of Moving Water

SINCE reading the interesting accounts of this phenomenon by Prof. W. Schmidt[1] and Prof. H. Stansfield[2], I have noticed several striking instances which yield a clue to their cause. They occurred on the surfaces of clear country streams bridged by planks that touched the water, obstructions which, mechanically, resemble the mill-stream example described by Prof. Stansfield. Evidently the macroscopic agent causing the sudden change in velocity need penetrate only to a very small depth.

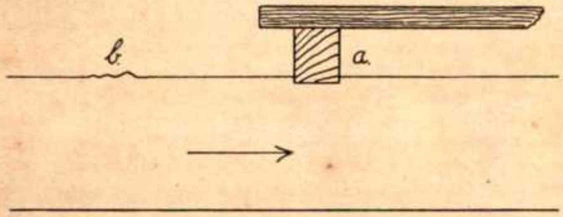

FIG. 1. Schematic diagram of stream (vertical longitudinal section); *a*, beam penetrating surface; *b*, surface line and secondary waves.

In the case illustrated, the 'line' was remarkably stable at an average distance of about 40 cm. from the bridge, and the conditions such as to be easily reproducible in a laboratory. The stream was about 1·3 m. wide and 40 cm. deep. The water flowed without visible turbulence and with a mid-stream surface velocity of about 25 cm. per sec. Fig. 1 represents a vertical, longitudinal section of the stream and foot-bridge, which touched its surface across the full width. Close to the line on the up-stream side was a series of parallel waves of diminishing amplitude and stationary with respect to the line. These secondary waves are clearly visible in the photograph (Fig. 2), and the reflections of overhanging foliage demonstrate the relative tranquillity of the surface between the line and the obstruction causing it.

In a wider and more slowly moving portion of the stream, a similar bridge had collected a band of scum. Here the line occurred nearly a metre above the scum, and secondary waves were visible only when the line was disturbed by winds, to which it was more sensitive than the line photographed.

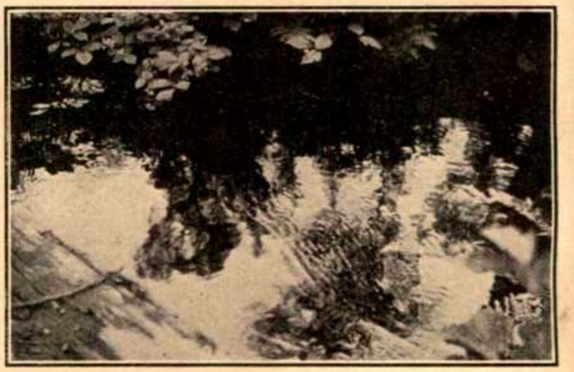

FIG. 2. Photograph of a particularly stable 'line'.

The experiments recorded in previous letters concerning the behaviour of floating particles and the effect of soap were repeated. The initial position of the line depends on the velocity of the stream, whilst the extent of its temporary displacement up-stream caused by substances affecting the surface tension depends on the velocity of the stream, and on whether the addition is made up-stream or down-stream relative to the line. Qualitatively, the observations, including the 'oil-patch' effect, are consistent with the idea that the line marks the boundary of a surface film of colloidally dispersed material under lateral compression caused by movement of the water.

Habit and Shell-shape in the Portuguese Oyster, *Ostrea angulata*

IT is known that the form of the shell of Portuguese oysters (*O. angulata*) living on the shore is different from that of individuals living permanently below tide-marks[1]. In the latter the shell is relatively very broad, in the former long and narrow, almost in the shape of a shoe-horn with the hinge at the narrow end. No explanation of this difference in shape could formerly be offered, but in a recent inspection of extensive inter-tidal beds of Portuguese oysters in the River Blackwater, to which I was courteously invited by Mr. Louis French, a probable explanation of the prevailing elongate-shaped shell suggested itself.

The oysters were lying on the normal muddy bed and had recently put on extensive new shell growth which was concentrated mainly at the end of the shell remote from the hinge; in almost all cases, the new growth was turned up from the substratum, whichever way the oyster was lying, so that in crossing the beds one walked on the sharp protruding shell-edges. As increments in shell-area are laid down by the mantle, this organ must be protruded mainly at the end of the shell, at least during growth, in a foreshore habitat. It seems probable that on the usual muddy foreshore bed the mantle is normally extended upwards in this part for feeding and respiration. Such a habit would give the advantage of an intake of clearer or less muddy water than is available around the more anterior edges of the shell which lie more or less in the mud, while if muddy water is inhaled the particles of foreign matter can readily be got rid of from a restricted region. If the normal habit is to extrude the mantle from the broad end of the shell as stated above, then it would follow that shell would be laid down with the mantle extended in this way and an elongate form of shell results. The sensory equipment of the bivalve is doubtless adequate to determine the most suitable region for intake of water.

On the other hand, in deep water where broad shells were found, the beds tend to be less muddy and the direction of the currents of water more regular; it is therefore reasonable to suppose that there is less need for restriction of the mantle opening in this habitat, and that the mantle will normally be more uniformly extended. In that event, new growth will not be concentrated at the broad end of the shell and a broader shell will result.

It seems, therefore, that a difference in habit of controlling the extension of the mantle in the two habitats may account for the difference in the shape of the shell. At least two factors appear to be concerned, namely, the nature of the substratum, and the simplicity or complexity of the water-currents in the respective habitats. Further researches on shell-shape of this and *O. virginica*, the allied American species, living on different types of substratum below low water, would be interesting; for the American species resembles the Portuguese form to a considerable extent in habitat and shell-modifications[2].

The variable sinuous or irregularly twisted elongate form of the shell seen more commonly in the cultivated Portuguese oyster is clearly due to the habit of adding large new shell-shoots mainly from the upturned broader end.

Life in the Dead Sea

THE remarkably high salt tolerance of unicellular organisms, which have been found in a saline lake of salt concentration so high as 19–26 per cent sodium chloride by Ruben Tschik, T. Hof, Baas-Becking and others, caused us to doubt the accuracy of the reputation of lifelessness, which tradition imputes to the Dead Sea. Accordingly, samples of Dead Sea water were taken under sterile conditions at a distance of 3–4 km. from the mouth of the Jordan at various sea depths up to 7 metres. The total salt concentration of the water samples was 28–29 per cent. Bacterial organisms could be grown in 1 per cent peptone sample water media at temperatures of 21°–23° C. and 30° C. from all the samples taken.

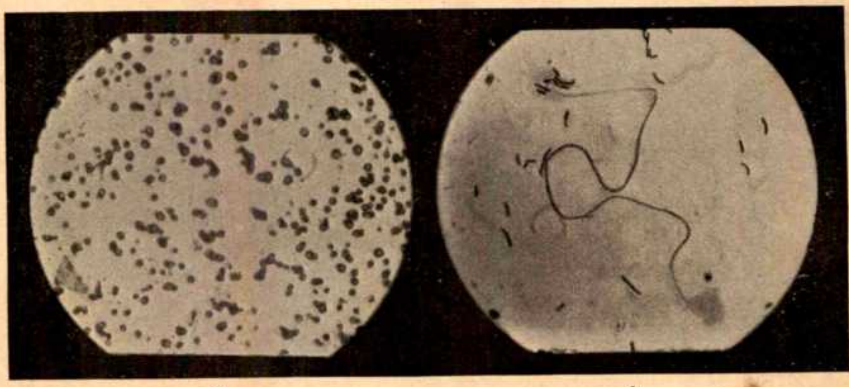

FIG. 1. Dead Sea micro-organisms. × 550.

In addition, microscopic examination of a hanging drop of the water revealed the presence of a living phytoflagellate 13μ long, which we believe is either a *Chlamydomonas* or a *Dunaliella*. Three micro-organisms have so far been distinguished: a yeast-like, Gram negative orange pigment producer $1 \cdot 6 \times 1 \cdot 6\mu$ (Fig. 1*a*), a Gram negative small rod-like organism $1 – 4 \cdot 8\mu \times 0 \cdot 8\mu$, and a Gram positive long filamentous organism (Fig. 1*b*) $3 \cdot 3 – 9 \cdot 9\mu$ to $170\mu \times 0 \cdot 8\mu$. The investigations are being continued.

We take this opportunity of expressing our thanks to Mr. M. A. Novomeysky, managing director of the Palestine Potash Co. Ltd., for his most kind assistance.

A New Blowfly attacking Sheep in Western Scotland

IT is now generally accepted that *Lucilia sericata* is the only species of blowfly which causes primary 'strike' of sheep in Britain. Although MacDougall (1909)[1] recorded instances of sheep being struck by *Calliphora erythrocephala* alone, the more recent investigations of Davies (1934)[2] in Wales, and of Ratcliffe (1935)[3] in Aberdeenshire, failed to reveal any primary species other than *Lucilia sericata*. The following record is, therefore, of interest.

In the course of an investigation of the blowfly problem, I have obtained, from Mull and western Argyllshire, several collections of larvæ taken from field cases of strike. The larvæ were in each case transferred directly from the sheep into metal containers filled with a sand-sawdust mixture. On arrival they were placed in breeding jars, of a type which prevented the possibility of contamination of the cultures by ovipositing flies. Out of thirteen batches bred out to the adult stage, seven were found to be pure collections of *Phormia terræ-novæ R.-D.*

I am indebted to the Natural History Museum for the identification of the species from specimens submitted. The batches were all obtained from blackfaced sheep in long wool; the strikes occurred on various parts of the body, for example, the throat, loins, tailhead, breech, etc. Each batch yielded anything from a dozen or so to more than three hundred individuals.

It would appear, therefore, that in western Scotland at least, this species acts as a primary blowfly, initiating strike on relatively clean-woolled areas.

The closely related species, *Phormia regina*, is the principal sheep blowfly of North America, but *Phormia terræ-novæ* has not been recorded previously, from any country, as attacking sheep. In view of its wide European and North American distribution, and of the newly emerged fact that it is able to strike sheep, the absence of any such records is a matter of considerable interest.

Temperature Coefficient of the Electrolytic Separation of the Hydrogen Isotopes

IN the course of an experimental study of the electrolytic separation of the isotopes of hydrogen at current densities of one milliamp./cm.^{2} and less with rigorous exclusion of oxygen, grease and other contamination, we have measured the temperature variation of the separation at mercury and silver cathodes with somewhat unexpected results.

The electrolyte was $0 \cdot 5N$ hydrogen chloride (with $0 \cdot 5N$ potassium chloride added in the experiments with mercury), and the anode consisted of the same metal as the cathode. The deuterium content of the cathode gas was determined by the micro-thermal conductivity method of Farkas[1]. The following values for the electrolytic separation coefficient (α) were obtained at 15° C. and 98° C.:

Cathode	15° C. (i)	15° C. (ii)	98°	98° (calc.)
Mercury	2·8	3·35	3·25	2·3
	3·1	3·25	2·95	2·5
Silver	7·0	6·5	4·6	4·6
	7·0	6·6	4·4	4·6

The two columns for the lower temperature relate to measurements made respectively before and after the high temperature measurements. The last column gives the separation factor that would be expected at 98° C. from the relation

$$\ln \alpha = \frac{\triangle E}{RT},$$

where $\triangle E$ is the difference in activation energy necessary to account for the separation factor (i) at 15° C. The probable error in the values of α is 2–3 per cent. The anomalous behaviour of mercury is remarkable, but might perhaps be accounted for by assuming that both of the alternative mechanisms ('catalytic' and 'electrochemical') of Horiuti and Okamoto[2] contributed to the cationic discharge, and that at the higher temperature the relative participation of the two mechanisms became more nearly equal.

With the view of testing this possibility, small quantities of α-naphthoquinoline, which might be expected to inhibit the 'catalytic' mechanism, were added to the electrolyte with the following results:

Cathode	Concentration of inhibitor	15° (i)	15° (ii)	98°
Mercury	2 millimols/litre	1·25	1·4	1·7
	0·3 ,, ,,	1·55	1·55	2·2
Silver	0·3 ,, ,,	1·7	3·0 falling to 2·3	3·7

The results for mercury, which incidentally show the lowest separation yet recorded, do not seem to fit in with the provisional hypothesis outlined above. The possibility that isotopic discrimination in cathodic reduction of the catalytic poison would account for the anomalous temperature variation seems to be excluded by the duration of the electrolysis.

The experiments are being continued and their possible interpretation will be discussed in detail elsewhere.

Raman Spectrum of Thiophosphoryl Chloride

THE Raman spectrum of phosphorus oxychloride has been explained by assuming an asymmetric tetrahedral structure for its molecules. The molecules of thiophosphoryl chloride may, by analogy with those of the oxychloride, be supposed to have a similar tetrahedral structure; and the Raman spectra of these two compounds should then be similar.

The following table gives the prominent shifts that I have observed in the Raman spectrum of thiophosphoryl chloride:

	$PSCl_3$	$POCl_3$[1]
A	171 cm.$^{-1}$	192·85 cm.$^{-1}$
B_1	246 ,,	267·39 ,,
B_2	382 ,,	337·44 ,,
C	432 ,,	486·24 ,,
D_1	543 ,,	581·2 ,,
D_2	750 ,,	1289·9 ,,

The data for the oxychloride are taken from Langseth's work[1]. The slight reduction in the values of the Raman shifts in thiophosphoryl chloride is presumably due to the substitution of the oxygen atom in the oxychloride by an atom of sulphur.

FIG. 1. Raman spectra of thiophosphoryl chloride ($PSCl_3$).

The shift $\Delta\nu = 1{,}290$ has been assigned to the P—O bond in the oxychloride[2]; the shift $\Delta\nu = 750$

in thiophosphoryl chloride can then be assigned to the P—S bond. The shifts $\Delta\nu = 171$; 246; 432 are very strong and the corresponding anti-Stokes lines excited by $\lambda = 4046$ can be seen in the spectrum.

A further study of the Raman spectrum of these two compounds as regards polarization and structure of the Raman lines is in progress, and the results of these studies will be published elsewhere.

Scientists and War

AT a meeting of prominent scientists held at Bangalore on August 22, under the joint auspices of the Institute of Chemistry of Great Britain and Ireland (Bangalore Branch) and the Society of Biological Chemists (India), to discuss the question of the moral responsibility of scientists in modern warfare, which has recently attracted much attention in these columns[1] and elsewhere, the following resolution was carried:

"This meeting while pledging its support to every united effort which can be made to abolish methods of warfare which are repugnant to the common instinct of humanity, recognizes that the more important objective is the abolition of war itself. To attain this end it would urge constant and strenuous activity on the part of thinkers and men of science. In particular, it records its opinion that more attention should be given by them to the study of the new economic conditions which of necessity accompany the advance of scientific research. Of equal or greater importance is the study of means for controlling the evil effects of mass suggestion by the more powerful agency of widely disseminated right ideas through the adoption of an international system of education."

C. N. ACHARYA.

Bangalore.
August 23.

Points from Foregoing Letters

FURTHER experiments on the production of photoelectrons in argon gas by X-rays, carried out by Dr. E. J. Williams and E. Pickup, support the quantum theory and the principle of conservation of energy, the applicability of which to X-radiation processes had been disputed, following upon the results of Shankland's experiments.

The radioactivity induced in silver at 20°, 77° and 290° K. by slow neutrons of different energies (groups *A*, *B*, and *C* of Amaldi and Fermi) has been determined by Drs. A. Arsenjewa-Heil, O. Heil and C. H. Westcott. They are led to conclude that the energies of groups *A* and *B* must be much lower than had been supposed, and that the absorption of boron is not inversely as the velocity of the neutrons.

The changes which sugar-like substances undergo in, or under the influence of, chick embryos of 4–6 days' incubation have been studied by Dr. J. Needham, W. W. Nowiński, R. P. Cook and K. C. Dixon, and compared with those effected by brain and muscle tissues. They find that the embryo does not glycolyse phosphorus-containing intermediate compounds; that glucose and mannose are the only sugars which give steady, long-continuing glycolysis; that the Pasteur effect is extremely marked; that the phosphorus distribution in various fractions is different from that obtained with muscle and brain preparations.

Referring to the reliability of different earthquake-registering stations deduced by Dr. H. Jeffreys, R. C. Hayes recalculates the values for the Pacific stations at Wellington and Christchurch; he finds that Wellington has a slightly greater reliability factor and considers that, in view of recent improvements, both stations should be included among those of good reliability. Dr. Jeffreys agrees that the order of reliability of Christchurch and Wellington stations cannot be definitely determined owing to the probable error involved in the calculations; he recommends that, for the time being, a 'weight' of 0·6 be accepted for Wellington observations.

Profs. W. Schmidt and H. Stansfield have described instances of the capillary wave that often appears when flowing water encounters an obstacle. Further observations are recorded by Dr. R. O. Hall, who suggests that the line marks the boundary of a compressed surface film of colloidal matter.

The difference in the shape of the shell of the Portuguese oyster, *O. angulata*, living on the shore, as compared with that of oysters permanently below tide-marks, is accounted for by Prof. J. H. Orton in terms of the surroundings. In deeper and less muddy water, the 'mantle' of the oyster, which secretes the shell, is uniformly extended and produces a broad shell; in the muddier tidal water of the foreshore, the mantle is probably protruded mainly at the end of the shell and an elongated form results.

Photographs of micro-organisms (three bacteria and a phytoflagellate) from the Dead Sea, where the total salt concentration is 28–29 per cent, are submitted by Dr. B. Wilkansky.

Dr. John MacLeod records *Phormia terræ-novæ R.-D.* as a hitherto unsuspected agent in the causation of cutaneous myiasis (attack on the skin by larvæ of flies) in sheep in Scotland (western Argyll and Mull).

H. F. Walton and J. H. Wolfenden have measured the temperature variation of the electrolytic separation of the hydrogen isotopes at mercury and silver cathodes, and find that the separation coefficient at silver falls with rising temperature while that at mercury is almost unaltered. Addition of a catalyst poison lowers the separation coefficient considerably and alters the sign of its temperature coefficient.

A reduction in the values of the shifts in the Raman spectrum of thiophosphoryl chloride, $PSCl_3$, as compared with phosphorus oxychloride, $POCl_3$, is found by Prof. V. N. Thatte.

Research Items

Blood Group Investigation

RECENT advances in blood group investigation have been reviewed by Prof. R. Ruggles Gates as a contribution to a volume commemorating the work of Miss van Herwerd on blood groups and eugenics in Holland (*Genetica*, 18, 1936. Manuscript received for publication, May 29, 1935). All the evidence indicates that in man the blood groups are mutations forming the mechanism of species modification of the non-adaptive category. The distribution of the blood groups in the anthropoids, when compared with that in man, on the hypothesis that *O* is the primitive condition in man, suggests that the development of the blood groups in both must be regarded as a case of 'convergent evolution'. It seems probable that a particular race in man in a particular locality developed the ability to produce the *A* mutation with sufficient frequency for it to spread without the aid of selection, but through a change in the mutation rate, which would be either gradual or marked and decisive, probably the latter. Recent developments have strengthened the view that the *A* mutation is much older than *B*, of which the occurrence is so low in peripheral peoples as to suggest that it is due to interbreeding with adjacent peoples. This view increases the difficulty relating to the *O* character of the American Indians, unless it be held that they are derived from primitive peoples who were isolated on the chain of islands from Sakhalin to Formosa and the Philippines, while *A* and *B* were spreading on the mainland of Asia. The aboriginal tribes of Formosa are still strikingly high in *O*. The occurrence of a high percentage of *A* in a group of "Blackfeet" can only be accounted for as an independent island of *A* mutations; and the *B* of the Caraja Indians and the Yahgans of Tierra del Fuego must be accounted for in the same way. Recent investigations in Africa suggest the probability that there have been three independent centres of *B* mutation, namely, the African negro, the Hindu and the Mongolian.

Arminghall Timber Monument

THE prehistoric monument at Arminghall, near Norwich, discovered by aerial photography in 1929, and excavated by Dr. J. G. D. Clark immediately before the Norwich meeting of the British Association last year, proves, like "Woodhenge" in Wiltshire, excavated by Mrs. M. E. Cunnington, to have been a circle in which the place of stone uprights was taken by wooden posts. The character of the monument in detail, its purpose, dating, and affinities, have now been made the subject of close study by the excavator (*Proc. Prehist. Soc.*, N.S. 2, 1; 1936). The monument consists of two concentric ditches separated by a bank, and surrounding a central portion, in which had been erected eight wooden uprights in U-shaped formation, and approached by a causeway interrupting the inner ditch. In this central area there was no sign of disturbance, excepting the post-holes and the ramps, by means of which the posts had been erected. The size and depth of the post-holes and the size of the ramps indicate that the posts were of considerable height—oaks, as shown by the charcoal found in the holes, probably of about a hundred years old. The absence of any burial precluded the idea that the purpose of the monument was sepulchral. The primary material obtained from the inner ditch consisted of 107 flints of indeterminate age, and fragments of hand-made 'rusticated' pottery, that is, pottery decorated with pinches or jabs, of a type to which the specific name 'Arminghall' is here given. On archæological evidence, this pottery is shown to date the monument as belonging to the Beaker period, as do other 'henges' in Britain which so far have been satisfactorily dated. Two hypotheses as to the origin of this class of monument are current—one that they are derived from the palisade barrows of the Low Countries, the other that they are degenerate megalithic cairns; but at present there is no decisive argument in favour of either.

Coloration of Nest Linings and Nestlings

DR. JEAN M. LINSDALE has noted a correspondence between the colour and tint of the linings of birds' nests and of the down of the nestlings themselves, especially in the Great Basin of the western United States. Further, these are both correlated with the kind of cover at the nest side and with the general climatic ranges of the birds (*Condor*, 38, 111; 1936). Apparently these species of birds which nest in exposed situations and live in hot regions have pallid nestling plumages and nest linings which reflect and counteract the harmful effect of the sun's rays. Species which live in the opposite conditions have dark colours in down and nest, so that they are able to absorb and take advantage of the warmth of the sun's rays.

Habits of American Sunfishes

THE American sunfishes excavate nests in shallow places, usually on sandy shores, which are familiar objects in late spring and early summer. Mr. C. M. Breder in his paper "The Reproductive Habits of the North American Sunfishes (Family Centrarchidæ)" (*Zoologica*. Scientific Contributions of the New York Zoological Society. Part I, Nos. 1 and 2, 21, 1936) brings a large amount of material together with special reference to reproductive behaviour of these fishes, which is closely similar in all genera. The male constructs the nest and guards the eggs. The female is only concerned with their deposition, her behaviour being very characteristic as she approaches the nest when sex recognition takes place. The primitive forms make the most elaborate nests, and there is more parental care in these than in the higher forms, the nests of which are much simpler. Broadly speaking, the annual cycle of habit in the family shows an interesting series of items of behaviour largely controlled by temperature, and the position and form of the nest depend on a variety of purely physical factors in the environment which include temperature, sunshine, depth of water, rate of flow, nature of bottom and proximity of protecting objects. This is a very interesting study embracing much previous work as well as a great deal of first-hand information.

The Chordate Head

THE problem of the constitution of the head region in the Chordates is discussed in a fully illustrated article by de Lange (*J. Anat.*, July 1936) based upon three lectures delivered at King's College, London. The vertebrate embryo is regarded as consisting of two portions: a non-metameric part, the gut, splanchnopleura, ventral body wall, brain region and the anterior cephalic mesoderm, arising in a similar manner to the three-layered, unsegmented larva of the invertebrates; and a dorsal, more or less segmented portion, the episome, having no homologue in invertebrates. The episome is pushed in a caudal direction in the Urochordata, in an anterior direction in the Cephalochordata, and in the true vertebrates it penetrates into the posterior part of the head region. This superimposed, axial episome has arisen and become segmented in conjunction with the need for locomotor efficiency. The axial musculature spreads over the trunk and into the head region. The branchial mechanism is afterwards formed, but it is in no way dependent upon the original metamerism of the episoma. As the head constitutes a structure for the gathering of sense organs, for presenting a firm front to the resistance of the water during locomotion and as a base from which the undulatory locomotor movements can take origin, its episomatic constituents lose their segmental structure. Some evidences of it remain, however, in the histological and functional character of the musculature. The hypobranchial muscles retain the metameric character of the invading episomatic mesomeres and of their cranial nerves.

A New Type of Apospory in Ferns

MISSES I. ANDERSSON-KOTTÖ and A. E. Gairdner (*J. Genetics*, 32, No. 2), investigating the inheritance of apospory in the hart's tongue fern, describe a form known as *peculiar* which arose from spores of the variety *crispum muricatum*. This peculiar type of sporophyte only attains a height of 8 cm. and may bear twenty-five fronds at one time. There is a complete absence of sori, sporangia and spores, the fronds producing aposporous prothalli which bear sex organs and undergo fertilization. As there is no meiosis, the chromosome number increases from $n = 30$ (normal) to a maximum of about 110. Various lines of evidence indicate that the chromosome number is frequently diminished in some way at the formation of the sex organs, but no cytological indication has yet been found as to how this takes place. In crosses between peculiar and normal, the former type of life-cycle is shown to be controlled by a single recessive gene. Heterozygous sporophytes are thus normal in appearance, but they sometimes show a feature which is new in ferns, namely, sori containing some normal sporangia and others which produce spermatozoids. The heterozygotes thus show incomplete dominance as regards the time of sex differentiation, which takes place both in sporangia and in the gametophytes. The conclusion is reached that the sporangial stage in normals is represented by the sexual stage in peculiars, and that a reduction division is therefore attempted at the sexual stage in the peculiar. These results have a bearing on various questions of apogamy, apospory and life-cycles in plants.

Properties of Oak

No. 11 of *Research Records* (Timber Series No. 3) contains a pamphlet on "The Properties of Home-grown Oak" (London: H.M. Stationery Office, 1936). It is stated in the pamphlet that in the past there has been much difference of opinion as to the merits of the timber, and this is largely attributable to its properties varying considerably with the conditions under which the trees are grown. The writer of the pamphlet appears to consider that there is little difference between the timber of the pedunculate and sessile oaks. By the purely practical test of felling and conversion in the forest, many hold the opinion that the timber of the sessile oak is more easily workable than that of the pedunculate. During the Napoleonic Wars, the finer lines of the French ships captured and the more artistic nature of their fittings were attributed to their having been constructed of the sessile oak, whereas the English ships were most usually constructed of the pedunculate or robur oak, a more stubborn and rugged grower. The pamphlet deals with the general properties and structure of the wood, seasoning, mechanical properties, durability and working qualities. A comparison of home-grown oak and American oak is made, and insect and fungus pests are discussed.

Inheritance in Cotton

INHERITANCE of form and size play a large part in the improvement of commercial cottons. Dr. J. B. Hutchinson (*J. Genetics*, 32, No. 3) has summarized some of these results. He finds in Asiatic cottons a series of five multiple allelomorphs affecting leaf shape. Broad, laciniated and narrow leaf types occur in *Gossypium arboreum* in different crops, narrow leaf being absent from South India and rare in Burma; it occurs in Assam. Leaf shape is associated with corolla colour. Broad leaf is primitive, and two allelomorphic genes have arisen causing progressive narrowing of the leaf lobes. Both are widely distributed in the species, and in some circumstances one of them has a selective advantage over the broad. Another set of genes affects all foliar organs and not merely the leaves. The habit of the plants is determined by the length of the vegetative period, that is, the number of nodes on the main stem. This is followed by the formation of sympodia with a flower at every node. Wild cottons have a high primary node number, with late flowering. Interaction is indicated for various node number factors, some of which are linked with corolla colour and some with anthocyanin production.

Carolina 'Bays'

THE 'bays' of the Carolina coastal plain are great oval depressions, usually well-timbered, each of which is rimmed with a sand-ridge that is highest on the south-east side. Their peculiar and uniform shape, the prevalent orientation of their longest axes in a north-west to south-east direction, and the immense number of examples, suggested to Melton and Schriever that the bays had been caused by the fall of an immense shower of meteorites, during or possibly before the Pleistocene. In a recent issue of *Science*, Prof. D. Johnson has pointed out several objections to this hypothesis. The rims of the 'bays' are not composed of material thrown out of the bottoms by explosive impact, but consist of clean sand, such as might border a lake-beach. The major axes of some of the depressions follow a north to south direction, and at least a few trend from north-east to south-west. Such departures from the prevailing orientation are inconsistent with the meteoritic hypothesis. The area is underlain by thick beds of limestone in which caverns and sink-holes are common. Johnson considers that the 'bays' started as lakes in sink-hole basins; these afterwards drained, leaving their old beach-ridges where the prevailing winds had piled them. A book on the 'bays' from the pen of Prof. Johnson is in course of publication.

The British Earthquake of April 6, 1580

LITTLE has so far been known about this earthquake, one of the strongest ever felt in Great Britain, and in some ways not unlike the North Sea earthquake of June 7, 1931. Mr. R. E. Ockenden, however, has lately reprinted "Thomas Twyne's Discourse on the Earthquake of 1580" (Pp. 40+1 plate. Oxford: Pen-in-Hand Publishing Co., 1936. 5*s*.), the original of which is now very rare, though copies are to be found in the British Museum, Bodleian and Emmanuel College libraries. He has also given a most useful introduction and a bibliography of contemporary pamphlets and other works. From these, it appears that the earthquake was felt throughout the south-east of England, and so far at least as Oxford and Norwich, also in Flanders and the north-east of France. In Great Britain, several churches near the coast of Kent were damaged. Even in London, stones were shaken from St. Paul's Cathedral and the Temple Church, and an apprentice was killed by the fall of a stone from the roof of Christ's Hospital Church. Except perhaps at Calais, little damage to buildings occurred in France and Belgium. The sea was greatly disturbed, and it is probable, as Mr. Ockenden remarks, that the earthquake was of submarine origin, and that its epicentre was not far from the east coast of Kent.

Radio and the Sunspot Cycle

L. C. YOUNG and E. O. Hulburt (*Phys. Rev.*, 50, 45) have examined the correlation of radio transmission with sunspot activity over the years 1923–36. They find that the optimum radio-frequency for short-wave daylight transmission over a given long distance increases with the sunspot activity, and they derive a semi-empirical formula connecting these quantities. The correlation of the radio data with sunspot number is much better than with terrestrial magnetic activity or with the solar constant. The last fact suggests that the visible and infra-red radiation from the sun, on which the solar constant is based, does not vary in close accord with the ultra-violet radiation which ionizes the upper atmosphere.

Structure of Benzene

ALTHOUGH the essential correctness of Kekulé's hexagon formula for benzene, with alternate single and double linkages, has been established by intensive chemical and physical investigation since its enunciation in 1867, and crystal analysis has shown that the ring is very approximately a plane, yet there are several other alternative formulæ (Dewar, Claus, Ladenburg, Thiele, Baeyer). The quantum-mechanical treatment of the problem has been dealt with by Hückel (1931–32) and by Pauling and Wheland (1933). Certain difficulties, however, were encountered in the comparison of the results with those of lines of experimental investigation. One of the most important was the apparent discrepancy between theory and experiment in the comparison between infra-red and Raman spectra. In a series of eight papers (*J. Chem. Soc.*, 912–987; 1936), C. K. Ingold and several collaborators have re-examined the matter in the light of the results of long-wave spectroscopy, which includes a study particularly of the infra-red and Raman spectra and the vibrational structure of bands arising from electron transitions. An important extension of the experimental method consisted in the substitution of hydrogen by deuterium, which does not alter the electron wave functions, so that the effect on vibration frequencies arises solely from changes of mass. Most of the coincidences in frequency in the infra-red and Raman spectra are shown to be the result of using liquids, in which cohesive forces disturb the conditions of symmetry, and the conclusion is reached that there is no need to assume the absence of a centre of symmetry in the benzene and hexadeuterobenzene molecules. The D_{6h} model (plane regular hexagon) is supported, whilst the D_{3h} (Kekulé) model fails to show itself in any spectroscopic features, and there is no indication of the D_{3d} (puckered) model.

Automatic Control of Road Traffic

IN the *G.E.C. Journal* of August, F. A. Downes gives a brief exposition of the elements of traffic flow and the requirements of automatic mechanism for controlling traffic. In the United States, traffic engineers have recently formed an Engineering Institution to study traffic problems. In Great Britain, the problems are studied by the engineers of the Ministry of Transport and by the staff of engineering works manufacturing traffic control apparatus. Of these engineers, there is probably no one who devotes his whole time to a theoretical and mathematical study of the subject. The design of modern traffic integrators requires a special knowledge of the mathematics of probability, and much useful work is being done in this direction. Theoretically, the only limit to the amount of traffic that can be dealt with by a single lane of traffic is that set by the limiting speed of the vehicles. For given road friction, and for a given average brake-power, it can be shown that there is a clearly defined optimum speed at which the greatest amount of traffic will be passed in a single lane per hour. The generally accepted figures lie between 12 and 18 miles per hour. At the lower speed, vehicles have 15 feet headway, but at the higher speed of 18 m.p.h. a headway of so much as 30 feet may be required. An optimum speed of 15 m.p.h. is often given, but this refers to dry roads of average surface. Unless a non-skid road surface is provided, this figure may be considerably increased. At intersections the first essential is a means of indicating 'stop' and 'go'. Interesting suggestions are made for indicating how soon change-over of colour may be expected. The full green indication, for example, consists of three concentric luminous rings; when one third of the time of the green signal has elapsed there are only two rings visible, then after two thirds only one. Another device embodies a dial divided into two portions, one of which is painted red and the other green, the indication being given by a large hand travelling in the clockwise direction.

Hydrogenation of Coal: a French Process

THE hydrogenation of coal to produce liquid fuel is, as is known, a process now in technical operation. The French process as carried out at Béthune has been described by F. Vollette (*Bull. Soc. d'Encouragement pour l'Industrie Nationale*, 135, 353; 1936).

The coal and hydrogen must be brought into intimate contact by intense agitation, and the temperature must be increased progressively by passing the mixture through zones, sufficient time being allowed at 350° for pasty fusion and solution in the oil, and at higher temperatures up to 470° for the absorption of hydrogen. The apparatus consists of a bundle of long narrow tubes (*faisceau tubulaire*) united to one another by interior pipes like gas washing bottles, through which the hydrogen bubbles. The whole is heated in a cell of a coke furnace. The finely powdered coal is suspended in heavy oil and pumped at 200 kgm. pressure into the apparatus, where it meets a current of hydrogen from a compressor.

The volatile product, by cooling under pressure and removal of gas, is automatically divided into gas, heavy oil (at 300°) and light oil (atmospheric temperature). Very light petrol (5 per cent of the total light oil) is removed from the gas by adsorption on active carbon. Part of the gas is used for heating and part is mixed with the hydrogen. The heavy oil is used for the suspension of coal. The non-volatile product is partly hydrogenated with the heavy oil and partly carbonized to coke for making water-gas. The hydrogen is obtained from water-gas and steam and need not be pure: even coke-oven gas (50 per cent H_2) may be used.

The overall yield of light oil is given as 660 kgm. per metric ton of coal, and it contains 25–30 kgm. of phenol and cresols. Of this oil, 87·5 per cent distils below 300° and 27·5 per cent below 200°. The heavier fraction is further hydrogenated in the vapour phase under pressure in presence of a catalyst to give petrol, which is principally aromatic and hydro-aromatic. Lignite hydrogenates more easily than coal. From 660 kgm. of light oil, 460 kgm. of petrol are obtained, or 1 ton per 2·175 tons of coal. This requires 3,500 cu. m. of hydrogen, in making which 2·2 tons of coke are used. The steam used requires 1 ton of coal per ton of petrol and the electrical energy for compression of gas and works service consumes a further 2 tons of coal. Thus 7·375 tons of coal are used in making 1 ton of petrol, the calorific value of which is 20·75 per cent of the total fuel used.

Biology of *Tridacna* and its Relatives

THE largest bivalves in the world belong to the Tridacnidæ. They have always aroused much interest in conchologists although little was known of the living animals. Size is not the only distinction in the family, for Prof. C. M. Yonge[*] shows that they are unique among the Lamellibranchiata in the relation of the mantle and shell to the other organs, and in the universal presence of zooxanthellæ in the tissues. In his peculiarly interesting monograph, there is a large amount of new matter clearing up much that was puzzling in these gigantic molluscs, which are among the most conspicuous members of the fauna of coral reefs in the Indo-Pacific region. *Tridacna derasa*, the giant clam, may be 4½ ft. long: the largest lamellibranch ever evolved, and may weigh about 4 cwt. The largest specimens personally examined were a little more than 3 ft. in length, and were so heavy that the combined efforts of two men failed to raise them.

There are two groups in the Tridacnidæ, the smaller boring forms, living in coral rock, and the larger species lying free on the surface of the reefs. All these clams normally rest on the hinge side of the shell with the edges of the valves pointing upwards. The pedal aperture, when present, lies close to the umbo. Thus, "as a result of a turning movement in the longitudinal plane, the dorso-ventral relations of the visceral mass and associated organs, on the one hand, and of the mantle and shell on the other, have become . . . the exact opposite of those in other lamellibranchs". This has given rise to much controversy as to whether the visceral mass has moved relative to the shell or whether the mantle has moved relative to the visceral mass. Prof. Yonge is now in the position to prove that the latter supposition is correct, and in this he is in agreement with Lacaze-Duthiers.

It is, however, in the amazingly efficient partnership with the zooxanthellæ that these molluscs are of outstanding interest. On this depends the whole problem of feeding, structure and evolution. Immense numbers of these zooxanthellæ always occur in the Tridacnidæ, housed primarily in the blood cells of the inner lobes of the mantle edges on the dorsal side where they are fully exposed to the light. In *Tridacna* these lobes extend far over the free edges of the shell valves in life, exposing a broad sheet of highly pigmented tissue. In the allied *Hippopus*, where there are fewer zooxanthellæ, the mantle edges do not extend in this way, but the shell valves open to a greater extent. The zooxanthellæ are confined to the blood sinuses, and are invariably contained within amœboid blood cells. Conical protuberances on the mantle edge, carrying lens-like structures, hitherto regarded as eyes, are here shown to be means whereby the internal illumination of the mantle tissues is increased for the benefit of the zooxanthellæ. The phagocytes, carrying the zooxanthellæ from the mantle, surround the reduced diverticula and other regions of the gut and contain these algæ in all stages of digestion. *Tridacna*, and to a less extent *Hippopus*, consumes a number of these, so obtaining a significant amount of food.

---

[*] British Museum (Natural History). Great Barrier Reef Expedition, 1928–29. Scientific Reports, Vol. 1, No. 11: Mode of Life, Feeding, Digestion and Symbiosis with Zooxanthellæ in the Tridacnidæ. By Prof. C. M. Yonge. Pp. 283–321+5 plates. (London: British Museum (Natural History), 1936.) 5*s*.

The mouth is small, there is no sorting mechanism in the stomach, and the selective action of the gills and palps is highly developed, particles 14 µ in diameter being rejected. Assimilation and intercellular digestion take place in the much-reduced digestive diverticula and also in the phagocytic blood cells which may pass through the lumen of the gut. Indigestible material remaining in the phagocytes is presumably carried to the kidneys, which explains the abnormal size of these and the presence within them of a great number of large concretions.

The Tridacnidæ are profoundly modified for the housing and final digestion of the zooxanthellæ, and *Tridacna* may be considered the supreme example of the exploitation of associated algæ by an animal, although unlike *Convoluta roscoffensis* it never loses the power of holozoic nutrition, and so only the surplus zooxanthellæ are consumed. Experiments failed to reveal any significant production of oxygen or removal of carbon dioxide by the zooxanthellæ in the light, but they automatically remove all phosphorus excreted by the animal and even the phosphorus present in the water around. This may be the limiting factor controlling their abundance.

In no case known where there is a partnership of algæ with an animal has it been so highly evolved as in *Tridacna*, resulting in the actual farming of the zooxanthellæ by the mollusc. Every stage in the evolution shows a step towards this end. In a *Cardium*-like ancestor, it is suggested that the zooxanthellæ first settled in the region of the siphons, having been taken in with the food and so ingested by wandering phagocytes. This partnership being of advantage to both alga and mollusc, but especially to the latter, the mollusc became so modified in structure that the largest possible surface might be exposed in which the algæ could dwell near the light, whilst with a larger consumption of these the ordinary digestive organs were more and more reduced, a very good combined method of feeding being the result, the boring forms having evolved after this adaptation of structure and functions. It is found that boring is entirely mechanical and that the byssus takes an essential part in this process.

Bacterial Epidemiology and Nutrition

A TEAM of statisticians and bacteriologists who for many years have been investigating experimentally the spread of epidemics of bacterial diseases caused by *Bacterium aertrycke* and *Pasteurella muriseptica* in herds of mice under controlled conditions, have now summarized the results of their published work with the addition of some new observations, including an account of epidemics of ectromelia, a virus disease of mice[1].

To the epidemiologist the work is of great interest and value, and many important conclusions emerge from it. It is found that the average resistance of surviving mice increases with survival in a herd, but never becomes absolute, and in the long run the great majority eventually succumb to the reigning disease, nor will the disease ever normally die out provided the herd does not become too small. The increased average resistance displayed by surviving mice is attributed to natural immunization.

It is considered proved that artificial immunization does confer a high degree of resistance, being more effective in a virus condition like ectromelia than in a bacterial disease like mouse typhoid. Experiments on the influence of 'bacteriophage' on mouse typhoid yielded entirely negative results. It is considered that a major importance may be attached in the genesis of epidemics to the evolution or importation of 'epidemic strains' of particular bacteria or viruses, and that association of two infecting agents may play a part in determining the character of an epidemic.

It seems to be clear that the amelioration or disappearance of an endemic or epidemic infection is more often the result of a summation of effects, many of them unidentifiable, than of any single known factor.

Mr. Knight has recently brought together in convenient form the available information respecting bacterial nutrition[2]. Knowledge of the conditions favouring or inhibiting bacterial development is of importance in bacteriological technique and in the study and control of infective diseases and morbid states, as well as indicating relationships which suggest the possible evolutionary scheme of the bacteria, particularly as it relates to parasitism.

The report is divided into three parts, of which the first and longest gives a systematic survey of the known facts, and summarizes the chemistry of bacterial metabolism and the nutritional requirements of bacteria. In the second part, these nutritional observations are co-ordinated, a brief attempt is made to develop an evolutionary scheme, and the parallelism between nutrient requirements and the development of pathogenic properties and parasitism is illustrated. In the final part, methods are described by which bacteria may be 'trained' and 'adapted' to a simpler mode of life, and the mechanism of nutritional variation is discussed.

There is much in Mr. Knight's report of interest to the general bacteriologist, such as his critical review of the gaseous requirements of bacteria, the various methods that may be employed for the study of bacterial metabolism, and the differentiation of essential from accessory food substances in relation to bacterial growth.

German Chemists at Munich

NEARLY three thousand delegates representing thirteen different German societies took part in a national congress of German chemists held at Munich on July 7–11. Prof. P. Duden of Frankfort presided at the general meeting, which was welcomed by Staatsminister Herr Adolph Wagner. Dr. O. Nicodemus of Frankfort delivered an address on the development of the chemistry of acetylene and its national importance as a source of raw materials. From acetylene many derivatives of the vinyl group can be made, which can be developed by polymerization to a great variety of valuable synthetic products. Amongst these may be mentioned the unsaturated hydrocarbons isoprene and butadiene, from which synthetic rubber is made, and a chlorinated derivative, chloroprene, which polymerizes seven hundred times as fast as isoprene and gives rise to an oil-proof synthetic rubber. By varying the conditions of polymerization, it is possible to plan the synthesis of products possessing specified physical properties, so that the range of application of these products is increasing rapidly.

Prof. Noack of Berlin then addressed the meeting upon the chemistry and physiology of plant structures. Afterwards the Congress broke up into twenty sections, which met for the discussion of special subjects, full reports of which will be found in the August number of *Angewandte Chemie*.

Although the main interest of the Congress was in applied chemistry, we find that one section was devoted to the history of chemistry, and a proposal was made to undertake the complete documentation and collection of publications (or copies) relating thereto. In a paper by Dr. Theis of Mannheim, the discovery of catalytic activity was credited to Döbereiner, who described in 1823 the ignition of hydrogen at atmospheric temperatures in the presence of spongy platinum.

Reference can only be made here to a few of the subjects discussed during the sectional meetings. Prof. Hedvall of Göteborg and Prof. Jander of Frankfort discussed reactions between substances in the solid state, Prof. W. Kuhn of Karlsruhe the properties of thread-molecules in solution and Prof. Staudinger of Freiburg the chemistry of macromolecules. Dr. Bredereck of Leipzig described his work on the constitution of the nucleic acids and Dr. Seidel of Munich his synthesis of urobilin. In the sections on applied chemistry will be found numerous papers dealing with fuel-oils, colours, paints, dyes, foodstuffs, building materials, leather, photographic materials, agricultural chemistry and many other subjects.

A whole section has been devoted to the consideration of the rapidly increasing number of *Kunststoffe* or artificial products. Among those of practical importance we may mention the 'organic' glass of Dr. O. Röhm. This substance, which is free from silicates, is derived from α-methylacrylic acid. Esters of the acid are colourless liquids, which polymerize, under somewhat difficult conditions, to vitreous solids, possessing a very high degree of transparency and a low coefficient of expansion. These glasses can be bent and moulded into shape at high temperatures and can be used for making windows for motor-cars and aeroplanes. They can also be used for optical purposes and for the manufacture of apparatus, such as filter-presses.

Another artificial product of first-rate importance is the substance trolitul, formed by polymerization of the hydrocarbon styrene, which is distinguished from most other artificial resins by reason of its excellent insulating properties, resistance to wear and impermeability to water. Thus it can be moulded into insulators and is suitable for employment even where high frequencies are used. The growing use of artificial products in industry has given new interest to the scientific study of complex polymers.

Science News a Century Ago

Schönbein and Faraday

IN 1836, the long and interesting series of letters began between Schönbein and Faraday which extended over twenty-six years and was afterwards published with notes and comments by G. W. A. Kahlbaum and F. V. Darbishire. The first two letters were from Schönbein, who was then professor of physics and chemistry at Basle. The first was dated May 17 and the second September 12, 1836. Both dealt with experiments on the action of nitric acid on iron and the protective influence of a film of oxide of iron. The most curious thing Schönbein said he had observed was that iron wire could be made indifferent to nitric acid. Previous to this second letter, Faraday had communicated an account of Schönbein's investigations to the *Philosophical Magazine*, and in his letter of September 12 Schönbein wrote: "I feel much obliged to you for the kind manner in which you mentioned my late researches on iron in the philosophical Magazine. It is this kindness which encourages me to address to you a second letter on the same subject".

Worcestershire Natural History Society

UNDER the above heading, the *Analyst*, 5, 160 (1836), records: "The ceremony of opening the museum of this Society took place on the 13th of September; on which occasion upwards of eight hundred persons attended, including a large proportion of the inhabitants of the county and city distinguished for their literary and scientific attainments. The Bishop of Worcester entered the room about twelve o'clock accompanied by the members of the council and at the request of the Hon. and Rev. J. S. Cocks took the chair". His lordship in a short speech congratulated the members of the Society upon the completion of the building and then called upon Dr. Hastings to deliver the inaugural address, "which was listened to with marked attention, and frequently elicited very considerable applause". About a hundred members and friends afterwards dined together, some admirable speeches were made and it was gratifying, said the *Analyst*, "to observe the interest which the prosperity of the Society appeared to excite".

De la Rue on Voltaic Electricity

THE first scientific paper of Warren De la Rue (1815–89) was a communication to the editor of the *Philosophical Magazine* dated September 15, 1836, and entitled "On Voltaic Electricity, and on the Effects of a Battery charged with Sulphate of Copper". "The greatest effect," the author said, "being always produced in those voltaic arrangements where the chemical agent exerted an action on only one of the metals constituting the battery, it occurred to me to use a saturated and perfectly neutral solution of the electro-negative metal, provided the other was capable of effecting its decomposition. I therefore tried the effect of a saturated solution of sulphate of copper in an elementary voltaic battery of the ordinary construction". After describing various experiments with his battery, he said, "It is worthy of notice, that after the batteries have been in action some time, a large proportion of the sulphate of copper is expended, and replaced by sulphate of zinc, *yet the action continues the same*. This naturally suggests using a saturated solution of any neutral salt, common salt, for example, and adding merely as much as the solution of copper as will serve for the time required. . . . I intend trying this, as I am still pursuing my inquiries on this subject, the object of which is to simplify as much as possible the voltaic battery. . . ."

Death of Antoine-Laurent de Jussieu

On September 17, 1836, the celebrated French botanist, Antoine-Laurent de Jussieu, died in Paris at the age of eighty-eight years. The nephew of the three brothers Antoine, Bernard and Joseph de Jussieu, who all contributed to botanical science, Antoine-Laurent was born at Lyons on April 17, 1748. On leaving school at the age of seventeen years, he joined his uncle Bernard de Jussieu (1699–1777) who was then a demonstrator at the Jardin du Roi in Paris, and after taking a degree in medicine became an assistant in the same institution. The collection of plants at that time was arranged according to the system of Tournefort. It becoming necessary to rearrange them, Jussieu adopted a new system suggested by what his uncle had done at Trianon, and from this grew the natural system described by Jussieu in his book "Genera Plantarum" published in 1789, the year in which the Revolution broke out.

As with so many other men of science, Jussieu for a time found his labours interrupted by the political upheaval, and in 1790 he became a member of the municipality of Paris, of which Bailly was Mayor, and was charged with the direction of the hospitals and charities of the city. In 1793, when the Jacobins came into power, the Jardin du Roi was reorganized as the Jardin des Plantes and Muséum d'Histoire naturelle, and Jussieu was made professor of rural botany. His colleagues included Lamarck, Daubenton, Saint-Hilaire, Fourcroy and Brongniart. He afterwards became director and treasurer of the museum and a professor in the faculty of medicine. In 1822 he severed his connexion with the school of medicine and four years later resigned his chair at the Jardin des Plantes, and was succeeded by his son, Adrien de Jussieu (1797–1853).

The natural system of classification of plants introduced by Jussieu was not appreciated at first as it ought to have been, and it was not until the writings of Robert Brown (1773–1858) that it made any headway in Great Britain. Besides his "Genera Plantarum" Jussieu wrote many memoirs, in 1796 published his "Tableau synoptique de la méthode botanique" and in 1800 his "Tableau de l'école de botanique du Jardin des Plantes". A statue of him now stands in the vestibule of the botanical gallery of the gardens. His son, who also was director of the museum, died leaving no male heirs, and the family, which for a century had been an ornament of science in Paris, became extinct.

Societies and Academies

Paris

Academy of Sciences, July 20 (*C.R.*, 203, 217–288).

LUCIEN CAYEUX: The coproliths of the North African phosphates. These coproliths consist of calcium phosphate, almost entirely free from organic or mineral inclusions.

LOUIS BLARINGHEM: The temperature of the spadices of *Arum italicum*. The temperatures are higher than the surrounding air: possible reasons for this are discussed.

LOUIS BOUVIER: Observations from the crayfish on the constitution of the side of the body-wall in the Crustacea.

ALEXANDRE GUILLIERMOND and MLLE. N. CHOUCROUN: An attempt at electrophoresis in the interior of plant cells.

MENDEL HAIMOVICI: Integral geometry on curved surfaces.

NORBERT WIENER and SZOLEM MANDELBROJT: Lacunar Fourier series. Inverse theorems.

JEAN MANDEL: The crumpling of a tube in a resistant elastic medium.

ALBERT PORTEVIN and LÉON GUILLET, JUN.: The elastic modulus of certain definite intermetallic compounds. Of the six compounds studied, CuZn, Ag_3Sb and $MgZn_2$ obey the rule of mixtures, the others, $Cu_{31}Sn_8$, Cu_9Al_4 and $CuZn_3$ give elastic moduli 20–40 per cent higher than those calculated from the mixture rule.

CHOONG SHIN-PIAW: New systems of bands of selenious anhydride, SeO_2, of selenium, Se_2, and of tellurium, Te_2, in the ultra-violet.

NY TSI-ZE and CH'EN SHANG-YI: The displacements of the higher members of the principal series of rubidium by the rare gases. Study of the displacement of the lines of the spectrum of rubidium by helium (up to 12·75 atmospheres), neon (up to 13·59 atmospheres) and argon (up to 7·12 atmospheres).

ANDRÉ LALLEMAND: The application of electronic optics to photography.

JEAN REBOUL: A possible correlation between the intensity of the cosmic radiation and the velocity of certain chemical reactions.

PIERRE AUGER and MME. GRIVET-MEYER: Analysis of cosmic ray bundles by utilization of their divergence.

RENÉ DUBRISAY and JACQUES LEFOL: Study of the saline hydrates. The salt and a direct reading balance are placed under a bell-jar over a hygroscopic substance under reduced pressure, and the loss of weight studied as a function of the time. With crystallized copper sulphate over phosphoric anhydride, the curve of loss shows a sharp angle at $5H_2O$, and after ten days the weight is constant at $1H_2O$. Over dilute sulphuric acid (pressure of water vapour 0·85 mm.), $CuSO_4,3H_2O$ is the final product.

RENÉ DALMON: Heats of mixture of sulphuric and nitric acids free from water.

MLLE. VALÉRIE DEUTSCH: The adsorption of proteins. The serum albumen of the horse.

E. RINCK: Diagram of solidification and electrical conductivity of the potassium-cæsium alloys.

HENRI MOUREU, MICHEL MAGAT and GEORGES WETROFF: The two forms of phosphorus pentachloride. From a study of the melting and solidification curves of phosphorus pentachloride there would appear to be a modification in the molecular structure. This is in agreement with the results of the study of the Raman spectrum: the latter shows that dissociation into phosphorus trichloride and chlorine does not take place under the conditions of the experiment.

J. JARROUSSE: Oxidation of diphenylpyruvic acid.

RAYMOND QUELET and MAURICE ANGLADE: The synthesis of 1-methoxy-2,4-dimethylolbenzene and of some of its derivatives.

ANDRÉ MEYER and PAUL HEIMANN: The products of halogenation and of oxidation of 2,4-dihydroxyquinoline.

PIERRE CHATELAIN: The geometrical and optical study of the crystals of *p*-azoxyphenetol.

EDMOND ROTHÉ and MME. ARLETTE HÉE: Study of a zone of contact of granite-gneiss by the observation of penetrating rays.

HENRI JEAN MARESQUELLE and RAYMOND SCHNELL: Experimental study of the phases of cecidogenic action in a gall.

MME. SIMONE BELLUC, JULES CHAUSSIN, JEAN COTTET, HENRI LAUGIER and MME. THÉRÈSE RANSON: Urinary yield, total molecular diuresis and diuresis of the elaborated molecules.

NICOLAS BEZSSONOFF and MME. MÉLANIE WOLOSZYN: The reversible oxidation of vitamin C present in a biological medium or in pure solution.

ACHILLE URBAIN and R. CAHEN: The amount of protein compounds in the serum of some ungulates.

A. and R. SARTORY, J. MEYER and MLLE. M. J. MERGLEN: Thermostable activating factors of cryptogamic origin favouring the growth of bacteria.

JEAN LAIGRET and ROGER DURAND: Virus isolated from mice and refound in man in the course of vaccination against yellow fever.

ANDRÉ BOIVIN: The comparative behaviour of the endotoxins and exotoxins towards trichloracetic acid.

BARUCH SAMUEL LEVIN and IWO LOMINSKI: Attenuation of the virus of bird plague by X-rays.

Moscow

Academy of Sciences (*C.R.*, 2, No. 3, 1936).

N. KOSHLIAKOV: Integral for the square of Riemann's function.

S. U. UMAROV: The Brownian movement of a supported girder and the transverse vibrations of bridges.

S. A. ARCYBYSHEV, M. N. BOGOMOLOVA, N. V. BORISOV and I. CH. REPSHE: Penetration of copper and gold ions into transparent crystals of sodium and potassium chloride.

V. ANTONOV-ROMANOVSKIJ: Direct proof of the bimolecular scheme of the luminosity of zinc phosphate.

V. RASUMOVSKIJ: Intensity of the valence and the structure of molecules.

J. G. RYSS and N. P. BAKINA: Complex fluorides (2). Hydrolysis of boro-fluoride ions.

I. I. CHERNIAJEFF and A. M. RUBINSTEIN: Interaction of pyridine with the chloride and the bromide of blomstrand salt.

K. V. KOSIKOV: The influence of the age and sex of the germ cells on the frequency of mutations in *Drosophila simulans*.

N. I. SHAPIRO: Is there germ cell selection in *Drosophila melanogaster*?

P. O. VELTISHCHEV: The plant mites (*Tyroglyphidæ*, Acari) as the main cause of failure of root-caoutchuc plants in Transcaucasia.

P. S. CHANTURISHVILI: Experiments in changes of sexual cycle in certain tail-less Amphibia.

Sydney

Royal Society of New South Wales, July 1.

D. P. MELLOR and F. M. QUODLING: Optical properties and crystal structure of some compounds of the type R_xMX_4. The marked double refraction of many compounds of the type R_xMX_4 where M = Pt, Pd, Ni or Au, is attributed to the existence of strongly anisotropic square co-ordinated ions. As yet, the structure of relatively few of these compounds have been analysed, but where this has been carried out the crystal optics agree qualitatively with those to be expected from the structures proposed.

Tokyo

Imperial Academy, June 12 (*Proc.*, 12, 147–177).

T. KAWATA: Regular analytic functions in the half plane.

A. KAWAGUCHI: (1) Some intrinsic derivations in a generalized space. (2) Certain identities in a generalized space.

H. HOMBU: (1) Invariant theory of the integral $\int F(x, y, y', y'', y''')dx$. (2) Geometry of the integral $\int(Ly''' + M)dx$.

N. WATANABE and M. IMAIZUMI: Possibility of measuring a distance of 500 m. in terms of the wave-length of light.

T. KUME: Saturation of non-volatile substances in aqueous solution.

H. YABE and M. EGUCHI: Deep-water corals from off Owasi, Mie Prefecture.

Y. INAI: *Discosiphonella*, a new ally of *Amblysiphonella*.

S. ENDÔ: New fossil species of *Sequoia* from the Far East.

T. KOBAYASHI: Proparian genus of the Olenidæ, and its bearing on Trilobite classification.

Vienna

Academy of Sciences, June 18.

JOSEF SCHINTLMEISTER: Origin of α-rays of 2 cm. range. The α-rays of this range, which have been found by several authors, do not come from any known element with atomic number greater than 44; they are probably due to element 61.

H. MARK and G. SAITO: Fractionation of highly polymerized substances by colorimetric adsorption analysis (1).

H. DOSTAL and R. RAFF: Mechanism of polycondensation reactions.

E. BARONI and W. KLEINAU: Nitration of phenols in chloroform.

O. BRUNNER and W. KLEINAU: The material forming the retina (3).

O. BRUNNER and E. BARONI: The material forming the retina (4).

Forthcoming Events

British Association for the Advancement of Science (Blackpool Meeting)

Monday, September 14

At 10 a.m.—Prof. H. L. Hawkins: "Palæontology and Humanity" (Presidential Address to, Section C).

Prof. J. Hendrick: "Soil Science in the Twentieth Century" (Presidential Address to Section M, followed by discussion).

Dr. T. E. Allibone, Dr. G. W. C. Kaye, Prof. W. M. Thornton, R. Davis, Dr. S. Whitehead, C. W. Marshall: "Production and Technical Application of High Voltages" (Discussion: Section A).

Dr. D. A. Allen, Prof. W. J. Dakin, Dr. A. C. Stephen, J. A. S. Stendall: "Function of the Museum in Zoology" (Discussion: Section D).

At 10.45 a.m.—Dr. Ll. Wynn Jones, Prof. H. R. Hamley, W. A. F. Hepburn, Prof. J. Drever: "The Reform of the Examination System" (Discussion: Section J).

At 2.15 p.m.—W. Hammett, Dr. A. W. Greenwood, E. T. Halman, Dr. E. L. Taylor, A. J. Macdonald, J. Wilson, Dr. A. L. Romanoff: "Poultry Industry" (Joint Discussion: Sections D and M).

At 2.30 p.m.—E. H. Fryer: "Traffic Safety" (Discussion: Section G).

At 7.30 p.m.—P. A. Francis: "Applications of Science to Poultry Farming" (Public Lecture at Poulton-le-Fylde).

Tuesday, September 15

At 10 a.m.—Sir Frank Smith, Dr. L. J. Harris, Dr. L. H. Lampitt, Dr. F. Kidd, T. Herbert, Prof. H. A. Denham, Dr. A. J. Smith: "Chemistry and Food Science" (Discussion: Section B).

The Right Hon. Lord Horder, Dr. R. D. Gillespie, Dr. E. P. Poulton, E. M. Killick: "The Strain of Modern Civilisation" (Discussion: Section I).

At 7.30.—Prof. C. M. Yonge: "Common Shore Animals" (Popular Lecture at Fleetwood).

Prof. D. Fraser-Harris: "Joy in Scientific Discovery" (Public Lecture at Thornton Cleveleys).

At 8.15.—Capt. F. Kingdon Ward: "Plant-Hunting in Tibet" (Evening Discourse).

Wednesday, September 16

At 8 p.m.—Prof. Allan Ferguson: "Splashes and what they teach" (Public Lecture at Preston).

Royal Meteorological Society, Wednesday, September 16, at 8.15—(in the Lecture Hall of the Royal Society of Edinburgh, 22 George Street, Edinburgh)

Prof. F. Linke: "Moving Cloud Pictures"

R. H. Weightman: "Stratosphere Flight in America".

Institute of Metals, September 14–18.—Annual Autumn Meeting to be held in Paris.

September 14, at 8.—Prof. P. A. J. Chevenard: "The Scientific Organization of Factories" (Autumn Lecture).

Association of Special Libraries and Information Bureaux, September 18–21.—Annual Conference to be held in Balliol College, Oxford.

September 18, at 8.30 p.m.—Dr. Cyril Norwood: "The Library in the School" (Presidential Address).

September 19, at 9.30 a.m.—Symposium on "Library Instruction for University and Research Students in America".

September 19, at 11.30 a.m.—W. H. Johnston: "The Collection of Information for the Commercial Pages of a Great Daily Newspaper".

September 19, at 2.30.—Colonel L. Newcombe: "Union Catalogues, National and Regional. Their Preparation and Utilization".

September 19, at 8.30 p.m.—Prof. A. M. Carr-Saunders: "The Need for the Centralization of Information on Social and Economic Surveys".

September 20, at 9.30 a.m.—B. M. Headicar: "Government Publications, British and Foreign. Their Collection, Classification and Utilization".

September 20, at 11.30 a.m.—Dr. J. Edwin Holmstrom: "A System for Card-indexing Abstracts and Research Data, with Instantaneous Cross Reference".

September 20, at 8.30 p.m.—J. Grierson: "The Film in Industry: the Development of the Documentary Film and its Growing Use in Research and Advertising".

Science and Culture

THE part played by science in modern life, and the greater part it should play, are themes that offer appetizing food for thought to those engaged in scientific pursuits; but most laymen "look up and are fed not", regarding science as something abstruse and esoteric, and remaining content to enjoy its benefits without inquiring into their past or future. All devotees of science will therefore welcome the renewed efforts which the British Association is making to bring home to the public the nature and magnitude of the services rendered by science to the community, and the ways in which science enters into, and maybe colours, their daily life.

The most obvious effects of science upon man are the directly material: food, clothing, shelter, and so on. Less obvious are its effects upon social and economic conditions, due largely to developments in the use of steam, water, electricity and mineral oil as sources of power. The least obvious influence of science upon man is the way in which it has revolutionized his general intellectual outlook (*Weltanschauung*). It is to this last aspect that we would here direct attention, our reflections thereon having been prompted by the address with which Sir Richard Gregory opened the discussion on "Cultural and Social Values of Science" at the Blackpool meeting of the British Association.

One of the handicaps under which the man of science labours in communicating his thoughts to the outside world is the necessity for using abstract terms that defy precise definition. He may use far too many of them, but he must use some; so to avoid misunderstanding and confusion of thought, it is always desirable to start with a preliminary explanation of the meaning of the chief abstract terms he intends to employ. The word 'science', for example, is used very loosely in everyday life: to some it signifies a kind of magic—sometimes 'black' magic; to the schoolboy it is 'stinks' or 'bugs'; to many educated people it is an esoteric and recondite activity that touches human life but fleetingly and tangentially; the journalist uses it in describing boxing, cricket and other pastimes, and the advertiser in any way that helps to sell his wares.

For most people, probably the best definition of a science is 'a body of accurate knowledge', obtained by observation, often under experimental conditions, and sound reasoning. It would be going too far to elaborate this definition by discussing experimental technique, the nature of theories and hypotheses, and the kinds of reasoning, inductive and deductive, used by the research worker; but in any event effort should be made to disabuse the mind that science is a dull, lifeless thing, and that scientific workers are merely highly organized automata. Success in scientific inquiry, it might be pointed out, implies the possession of some of the higher human qualities, such as courage to look facts squarely in the face and to accept conclusions even when they are unpleasant or subversive of established practice and belief; patience; a disciplined imagination; an open mind and a critical outlook; and, perhaps the greatest of all, the artist's sense of striving for perfection.

Culture resembles science in having its roots in accurate knowledge and in critical thought. It is, however, more than knowledge or learning (a small amount of learning is compatible with a high degree of culture), because in concentrating on "the *best* that has been thought and known in the world", it becomes essentially a study of perfection. Culture has therefore close affinities to science, art and ethics. Matthew Arnold, the nineteenth-century apostle of culture, took the view that the pre-eminent part of culture is not "the scientific passion, the sheer desire, to see things as they are", but such ethical elements as love for one's neighbour, beneficence, the desire to remove human error, confusion and misery, and the noble aspiration to leave the world better and happier than we found it.

The distinguishing feature of science would thus appear to be accurate knowledge, and that of culture to be taste, judgment or discrimination between the true and the false, the good and the bad, the beautiful and the ugly. Were Matthew Arnold living to-day, he would readily acknowledge the benefits that science has conferred on humanity in the directions he indicated. Has it not exposed many causes of human error and dissipated confusion of thought ? Has it not done wonders in preventing, alleviating and curing physical pain ? Has it not provided man with the physical means towards a fuller and richer life ? If science has not made man ethically better, that is not the fault of science, for it may be claimed that the golden rule of conduct—consideration for others—which is the foundation of morality and the non-material basis of happiness in communal life, is a valid scientific deduction from the data of experience. Emotion being a more potent factor in conduct than knowledge (*Pour faire quelque chose de grand il faut être passionné*), the contributions of science to "the good life" may compare unfavourably with those of art and religion, but it will be agreed that no conduct can in effect be good unless it conforms with the dictates of reason.

The influence of science upon the development of man, both as an individual and as a member of society, is apt to be overlooked by the historian. The pioneers of natural science, like Copernicus, Galileo, Bacon, Descartes and Darwin, by overthrowing the geocentric and anthropocentric doctrines of their times, and by establishing belief in the constancy of the order of Nature, freed the human mind from the fetters of dogma and unreasoning faith, and opened up possibilities of knowledge and attainment that we are now only beginning to realize and explore.

The services of these men, and of many others who have contributed to our knowledge of the universe and to the liberation of human thought, should be taught and discussed in our schools, and, generally, our educational curricula should be re-oriented in the direction of greater concentration upon the best that has been thought, known *and done* in the world, irrespective of time and geographical location. Our teachers need to be men and women of higher culture, seeking to emulate the great men of culture, who, as Matthew Arnold said, "have had a passion for diffusing, for making prevail, for carrying from one end of society to the other, the best knowledge, the best ideas of their time ; who have laboured to divest knowledge of all that was harsh, uncouth, difficult, abstract, professional, exclusive : to humanize it, to make it efficient outside the clique of the cultivated and learned, yet still remaining the *best* knowledge and thought of the time, and a true source, therefore, of sweetness and light".

The question arises, therefore, whether bodies like the British Association and the Royal Society cannot, in conformity with their statutes, tread the path of the diffusion of natural knowledge with greater vigour than heretofore. Neither body issues a publication which really hits the educational bull's-eye. The Association, it is true, enjoys what is called 'a good Press', but unfortunately that Press, in pursuit of commercial aims, largely selects matter that is calculated to create a sensation, and which seldom leaves a lasting impression.

We therefore suggest that the Council of the Association be urged to consider the advisability of publishing on its own account a special volume, to be available at a low price, containing those addresses, lectures, papers and discussions, or parts of them, which have a direct bearing upon the life of the community, and including descriptions of discoveries and inventions, new light on old truths, economic and social problems, and contributions to higher thought. Authors could be advised in advance that their contributions were ear-marked for dissemination among the public, and that therefore they should be written so far as possible in non-academic language, with a non-academic approach, and with the express object of arousing interest in and appreciation of the social and cultural implications of scientific research among those who are still largely ignorant of or indifferent to it. The first quinquennial review of the progress of science, prepared for the Association by a number of authors, and shortly to be published, though not entirely of this character, should be of great service in extending interest in scientific knowledge and achievement. Our hope for the future lies in enlightened education of this kind.

Petrology and Movements of Snow Deposits

Snow Structure and Ski Fields: being an Account of Snow and Ice Forms met with in Nature and a study on Avalanches and Snowcraft. By G. Seligman; with an Appendix on Alpine Weather, by C. K. M. Douglas. Pp. xii+555. (London: Macmillan and Co., Ltd., 1936.) 25*s*. net.

OF all superficial deposits, that of snow is in its physical nature the most inhomogeneous and changeable, chiefly because it exists at temperatures so close to its melting point that melting, evaporation and sublimation are ever at work within the porous mass, modifying the characters of layers which were themselves distinctive when laid down. In consequence it is extremely difficult to predict the behaviour of snow on slopes, and losses in life and property due to avalanching are severe. Long experience has supplied a wealth of precepts to be followed by the wise snowcraftsman, but the reasons for them are imperfectly understood. The properties of the snow are determined by those of ice at the temperature involved, by the shape of the individual grains, their degree of interlocking and the cohesive force uniting them, whilst a further important control may be exercised by the presence of water. Mr. Seligman seeks to interpret avalanche lore in the light of our knowledge of the structure of the snow on deposition and its transformations under varying conditions, and he paints a vivid picture of the complexity of the problem.

The insufficiency of the available data is apparent, and it relates to both laboratory and field investigation. It is surprising that we should still be in almost complete ignorance of the properties and stability conditions of the vitreous state of so fundamental a substance as water, and much remains to be learnt regarding the internal structure and temperatures of accumulations of snow and ice. Only recently, Prof. H. U. Sverdrup has obtained evidence for the unexpected conclusion that in Spitsbergen, where the average annual temperature is − 12° C., the glaciers with the exception of a superficial layer subject to seasonal variation are at a temperature of 0° C. throughout, so that only the latent heat of fusion is wanting to remove them. The present work, which deals with the development of snow through all stages to compact ice, makes an opportune appearance in view of the increased attention now being directed to the subject as witnessed by the meeting of the International Commission of Snow in Edinburgh this year. Lavishly provided with beautiful illustrations, it should perform a valuable service in enlisting the interest of snow sportsmen in theory and observation.

Lack of precision in the terminology of the multitudinous forms of ice deposits has been responsible for much confusion in the past, and the author's definitions and analysis of foreign usages should pave the way for more fruitful discussion in the future. The classification and terminology adopted is on the whole satisfactory, although views will differ on details: thus the restriction of the 'glacier proper' to a moving mass of ice the surface of which is bare in summer, although convenient for the snowcraftsman, will not be acceptable to the geologist and physiographer. A somewhat careless employment of the terms 'condensation' and 'sublimation' will puzzle the non-specialist whom the book is cunningly devised to attract—the formation of super-cooled water drops is not a sublimation process—and it would be wise in view of the wide constituency addressed to limit 'condensation' to signify the passage from vapour to liquid only.

Mr. Seligman gives an admirable digest of the huge and undisciplined literature on snow and ice, and the arduous nature of his own field researches may be illustrated by his statement that on one occasion he spent two hours on a cornice in a fifty miles an hour gale attempting to make microscopic observations, all but a few minutes, however, being occupied in restoring circulation! The number of factors governing the form and interrelationship of the granules of a snow deposit is very great, and meteorological conditions exercise an important control over the processes active in the uppermost layers, whilst through the agency of freezing percolating melt waters, surface heat is delivered to the deeper layers and their structure modified. Snow phenomena provide Nature's greatest display of sublimation, and the author convincingly demonstrates the important role it plays in the development of structure, whereas regelation, which was formerly called in to explain many things, is now considered to be of minor application.

The origin of many avalanches is bound up with the stratification of the snow, in which beds laid down and altered under different meteorological conditions, and consequently of varied structure and properties, are insecurely welded to each other, and the elucidation of these matters properly belongs to the province of stratigraphical and metamorphic geology. Mr. Seligman's book provides a stimulating record of the advances which have been made towards the solution of the problem of deducing meteorological history from the petrography of the deposits, and conversely the prediction of structure and mechanical properties from knowledge of past conditions. The perusal of Part 3, which treats of the different kinds of avalanches, the precautions to be taken in the hope of escaping them, and the procedure to be followed in attempting to rescue unfortunate victims, cannot fail to impress the reader with the hazardous nature of the snowcraftsman's exercise. The timid will keep away from the snow mountains, but happily for the growth of knowledge there are others.

Poverty, Malnutrition and Disease

Poverty and Public Health
By G. C. M. M'Gonigle and J. Kirby. Pp. 278. (London: Victor Gollancz, Ltd., 1936.) 6*s*. net.

IN producing the book under notice, Dr. G. C. M. M'Gonigle and Mr. J. Kirby have made a practical and notable contribution to the study of community and family nutrition, which should help responsible authorities and individuals to acquire a true perspective and a sound sense of values in regard to the many factors which collectively influence the health of the general public. The authors write with the authority of first-hand experience. For many years their official duties have brought them face to face with the realities of poverty, malnutrition, disease and death in the depressed areas, and in the course of their work for the health and welfare of the local community in Stockton-on-Tees, they have collected data, instituted inquiries and made original investigations into the nutritional state of children and family health and economics.

Such is the background of knowledge and experience behind the publication before us. It has appeared at a time when the national conscience is alive to the significance of diet to health, and the fact that malnutrition is not merely a problem to be solved by satisfying hunger. The health and fitness of the nation are primarily determined by the state of nutrition of the people, and of necessity the food consumed by the individual child or adult must be physiologically adequate in respect of quality, quantity and balance if optimum nutrition is to result.

The book opens with an examination of available information relating to the physical condition of the adult population and the health records of elementary school children. The findings of the Ministry of National Service (1917–19) are reviewed, and the data revealed by the routine medical examination of elementary school children and special investigations are dealt with in detail. It is pointed out that in 1933 no less than 3,094,926 children, or 61 per cent of the average attendance at elementary schools, were subjected to examination by school medical officers, and that of these, 1,140,445 children, or 36·8 per cent of those examined, showed defects requiring treatment or calling for careful observation. The chapter dealing with child welfare records is of particular interest. In it the authors have presented a careful analysis of the data of 741 children who attended the child welfare centres in Stockton-on-Tees. They have correlated the incidence of defects with the evidence collected in regard to satisfactory or unsatisfactory diets. Bone defects, pharyngeal conditions, dental decay and anæmia were markedly more prevalent among the children whose diet was judged unsatisfactory. Attention is directed to the common error of including an excessive amount of carbohydrate food in the diet of children, and it is recorded that in Stockton-on-Tees a reduction in carbohydrate food coupled with an increase in protein, fat and vegetable constituents was followed by a decrease in rickets and other defects attributable to sub-optional nutrition.

A large section of the book is devoted to a critical analysis of the data obtained in Stockton-on-Tees of 152 families subsequent to being rehoused on a new housing estate. The health, mortality records and economic circumstances of these families are compared with those of 289 families which were not transferred to the new housing estate. The dietaries of the families in the two groups are examined, and it is held that the increased cost of rent on the new housing estate accounted for the unsatisfactory diet purchased. The intimate details of family budgetary expenditure are examined with great care and thoroughness. It is pointed out that in addition to rent, many other items in the budget are unavoidable, and their payment of necessity limits the money available for the purchase of food. In particular, the case of the unemployed is dealt with, and the book concludes with the well justified suggestion that the data presented are of sufficient importance to warrant further investigation and inquiry.

Quantum Electrodynamics

The Quantum Theory of Radiation
By W. Heitler. (International Series of Monographs on Physics.) Pp. xi+252. (Oxford: Clarendon Press; London: Oxford University Press, 1936.) 17*s.* 6*d.* net.

THE quantum theory of the electromagnetic field is without doubt the 'difficult child' of quantum mechanics, which in spite of many attempts at improving it, has retained all the disquieting and unpleasant characteristics which it showed from its birth. There is a number of physicists who refuse to discuss it because, as they would put it, (*a*) it is unnecessary, since all its correct results can be derived by simple means; (*b*) it is wrong, because its application to problems like the self-energy of the electron leads to contradictions; and (*c*) it is extremely complicated.

In face of this opposition, it requires courage to devote a book to an exposition of this theory and its main applications. However, Dr. Heitler has a strong case against the opposition; for as to objection (*a*), the 'simpler' methods, namely, the quasi-classical introduction of the field in calculating the absorption, which is then related to the emission by means of Einstein's law, is, in fact, completely equivalent to quantum electrodynamics, both in the assumptions and in the procedure. Indeed, Einstein's law is based on Planck's radiation formula and thus on the concept of the light quantum, and therefore contains no more and no less than quantum electrodynamics itself. If we applied the 'simpler' procedure consistently, we should arrive at the same contradictions as in the usual form of quantum electrodynamics. Which of these methods one prefers is a matter of taste, but quantum electrodynamics has the advantage that, instead of requiring a new 'recipe' for each new type of problem, one can develop a general scheme to deal with all kinds of radiative processes and, from this, solve special problems by merely inserting appropriate values into the general formulæ. The importance of such a general scheme is emphasized by Dr. Heitler, and this will make his book very valuable in dealing with practical problems.

As for the argument (*b*) that the theory leads to inconsistencies, this is undoubtedly true. But as Dr. Heitler points out, we can always pick out those terms in the solutions which are significant as opposed to those which are due to the self-energy and do not correspond to reality. Thus in all practical applications we can obtain a definite answer, provided we do not require an accuracy exceeding a limit determined by the ominous number e^2/hc or 1/137. In all cases, except possibly where very high energies are involved, these predictions agree with experiment, and we believe that whatever may be the form of a future theory, it is not likely to alter these predictions except for corrections of higher order in e^2/hc. This fact in itself justifies an account of the theory and its applications.

Nevertheless, we should keep in mind that the theory is, strictly speaking, inconsistent, and if Dr. Heitler calls it "the reasonable quantum theoretical extension of classical electrodynamics in the same way as quantum mechanics is . . . the extension of classical mechanics" (p. 81) he is perhaps too optimistic.

As for the objection of being complicated, this only makes a clear and comprehensive treatment more desirable. Moreover, from a study of this book the reader will find that although one cannot exactly call radiation theory an elementary subject, it is very much simpler than it would appear from most of the original papers, which —with few exceptions—were unnecessarily complicated.

The book starts with a short account of the classical theory of radiation, emphasizing the difficulties connected with the structure of the electron. The second chapter deals with the quantization of the field *in vacuo*, and contains an account of Bohr's work on the uncertainty relations for the field strengths and the limits of accuracy with which these may, in principle, be simultaneously measured. Then the terms describing the interaction with matter are introduced, and general formulæ for the probability of any radiative process are derived. Emission, absorption, photo-electric effect, scattering, dispersion and Raman effect, etc., are then discussed as applications of these formulæ. Complete results are given for those phenomena that are of particular interest in dealing with hard γ-rays and fast particles. Chapter iv deals with the theory of the positrons and their creation and annihilation, while the last chapter deals with the passage of fast electrons and γ-rays through matter. The limitations and difficulties of the theory are then summarized again, together with a short note on Born's attempt to remove them.

The exposition is very clear. The reader is assumed to be familiar with ordinary quantum mechanics and classical field theory.

It is, of course, unavoidable that there should be a few minor points on which author and reviewer disagree (for example, the statement that the field fluctuations have no connexion with the zero-point energy, p. 67), and a few places which leave the reader puzzled (such as, for example, the dotted curve in Fig. 7, or that a formula which has been derived "agrees roughly with what we should expect", p. 170), but their number is small. They do not affect the value of the book, which will be indispensable to anybody interested in either the principles or the applications of radiation theory.

Chinese Materia Medica

Chinese Medicinal Plants from the Pen Ts'ao Kang Mu, A.D. 1596

Third edition of a Botanical, Chemical and Pharmacological Reference List. Compiled by Dr. Bernard E. Read. (Published by the Peking Natural History Bulletin, 1936.) Pp. xvi+389. (Peiping: The French Bookstore, 1936.) 6 dollars.

THE fact that this book, which gives the maximum of information in the minimum of space and therefore appeals only to experts, should have reached a third edition, is a striking testimony to the interest now being shown in the chemistry of plants. It is also a tribute to the learned author's success in accomplishing the remarkable literary and scientific feat of transmuting medieval Chinese materia medica into this thoroughly modern treatise on the medicinal plants of China. The data he has accumulated as a result of his labours are set out in tables giving the kind of information usually provided in books on materia medica, namely, botanical family, specific name, habitat, principal constituents, etc., but with the unusual addition of a bibliography of the chemical, medical and pharmacological literature of each drug.

Of the 898 drugs dealt with, many are either identical with, or closely related to, drugs still in use in Europe; others have long been obsolete in medical practice, and there are many which seem to be peculiar to China. None of the recognized cardiatonic drugs seems to have been used in China at the date, A.D. 1596, when this list was compiled. An interesting feature of the list is the inclusion of a considerable number of foodstuffs, especially fruits, nuts and cereals, a point to which Prof. Read directs particular attention as possibly indicating that the early practitioners had a sound, if empirical, belief in the importance of an appropriate dietary in the maintenance of health.

It is well known that Prof. Read's labours have already had the practical outcome of extending enormously the use of the alkaloid ephedrine throughout the world, but he probably has small hope of achieving similar triumphs with other constituents of Chinese drugs. At the present time, the investigation of natural drugs on the basis of local belief in their therapeutical value seems to be almost confined to Soviet Russia, Japan, China and India, and though interesting results have been obtained in all these countries, results of practical value, so far as additions to therapeutical resources are concerned, remain unimportant.

In other countries, work in plant chemistry is being carried on on broader and, in the writer's view, better conceived lines, in the correlation of components in allied species, the determination of the constitution of plant constituents and the investigation of the biological processes by which these substances are produced in plants. By these less direct methods much new knowledge is gained, and they are equally certain to lead in due course to the discovery of any still unknown plant constituents of therapeutic value.

To both the direct and the indirect worker in these fields, Prof. Read's book is a gift, the value of which can best be appreciated by those who have had practical experience in assembling all the relevant chemical, medical and pharmacological data regarding a single drug. To repeat the process with nearly nine hundred drugs, as Prof. Read has done, is to exhibit scientific altruism as rare as it is welcome. The careful and critical compiler rarely receives the credit he deserves for his indispensable work, and it must be some satisfaction to Prof. Read to be able to begin his introduction to the third edition with these words: "The large number of researches upon Chinese Materia Medica undertaken during the last decade necessitates a new edition of this reference list", for he is undoubtedly the cause of most of these researches, and his book may be cordially recommended as a source of information to any new worker who thinks of pegging out a claim in this field.

British Association for the Advancement of Science

A Scientific Survey of Blackpool and District. Prepared for the Blackpool Meeting, 1936, by various Authors. Edited by Arthur Grime. Pp. 152+3 plates. (London: British Association for the Advancement of Science, 1936.) n.p.

THE well-known British Association handbooks prepared annually for each centre visited have now for some years been issued in a uniform format, and if the appearance of the pamphlets is less impressive than the bound volumes of former days, the contents shows a marked improvement, and leaves little to be desired.

The handbook for the Blackpool meeting begins with an exhaustive survey of all aspects of the Fylde, illustrated by several useful maps. This includes chapters on the historical geography and the place names. A section of Lancashire sea fisheries follows. Then comes an account of the growth of Blackpool itself, from which we learn that there was a Blackpool of a few cottages so far back as the seventeenth century, and that the seaside resort began to be known in the eighteenth century. It was not, however, until the second half of the nineteenth century that the great growth set in. A full account is given of this growth and of the varied municipal activities of the borough. The coast defence works are also fully explained. Lastly come chapters on the geology and natural history of the Lake District, added no doubt in view of the excursions to that part of England. The book maintains the high standard of recent volumes in the series and reflects credit on its numerous contributors.

A Method of Illustration for Zoological Papers

By H. Graham Cannon. Pp. x+36. (London: Association of British Zoologists, 1936.) To Members, 2*s*. 6*d*.; to non-Members, 3*s*.

ALTHOUGH so much illustration of scientific papers is now performed by photographic methods there are still many cases where the process fails, such as complicated anatomical subjects, or those that present difficult problems of lighting or where a semi-diagrammatic treatment is called for. These require a selection and emphasis of parts which can still only be done by hand. The comparative ease and accuracy of the photographic process has done much to kill many of the older forms of art. Lithography, which in the past has produced such magnificent work, is almost as much a thing of the past as the woodcuts of Bewick. But as handwork is not, and never can be, entirely superseded, the student and advanced worker will be glad of any help that will get him over the technical difficulties in making his drawings. Everyone should at least try to produce his own illustrations with his own hand.

Prof. Graham Cannon has written a small booklet, published by the Association of British Zoologists, in which he claims that "any zoologist as long as he can draw a reasonably straight line . . . can turn out drawings that are really convincing". The method advocated appears sound and the illustrations of the method also appear convincing.

Bibliography of Soil Science, Fertilizers and General Agronomy, 1931–1934

Pp. xxxi+473. (Harpenden: Imperial Bureau of Soil Science, 1935.) 25*s*. net.

IN 1929–1930, eight Imperial agricultural bureaux were set up to act as clearing houses of information on different aspects of agricultural research and practice for the use of research and advisory officers in the Colonies and Dominions. One of their functions has been to issue abstracts of all the important papers and reports published in every country that bear on their respective subjects. The book under review is an index of all the papers abstracted by the Imperial Bureau of Soil Science, one of these eight bureaux, during the four years it has been issuing abstracts. It covers all the agricultural aspects of the work done in soil science, and in soil and crop management, but is only concerned with plant breeding, plant diseases or animal husbandry in so far as they depend on the soil or its management.

The book is an index of published papers. It gives the author, the title of the paper in English, the journal and the year in which it was published, but it does not give abstracts of the papers. The entries are grouped according to subject, or to the country to which they refer, and the subjects and countries are printed in the order of the numbers which they are given in the universal decimal classification. There is a detailed subject index running to fifty-five pages to enable one to find the number allotted to every subject, and it appears to be excellent.

There are three indexes, the subject index already noted, an index of all the journals quoted, and an author index. A minor criticism can be levelled at the author index in that it only gives one transliteration of a name from a non-Roman to the Roman alphabet, even though the author himself uses several.

E. W. R.

Principles of Electric and Magnetic Measurements

Part 1: Electricity, by P. Vigoureux; Part 2: Magnetism, by C. E. Webb. (The Student's Physics, Vol. 7.) Pp. xi+392. (London, Glasgow and Bombay: Blackie and Son, Ltd., 1936.) 20*s*. net.

THIS text has the advantage that the authors are at the fountain of standardization in electrical science at the National Physical Laboratory and their modern treatment of their respective subjects is thereby enhanced. They start off by carefully defining their units and one is pleased to note the adoption of the new scheme of units based on the kilogram-metre-second system which is to unify the theoretical electro-magnetic and practical electrical units throughout the world in a few years time.

The present interdependence of physics and electrical technology is illustrated by the space given to thermionic devices, quartz crystals, the precision measurement of frequency, and even the linear time-base is mentioned, although, for some reason, the latter is not included in the index. The text is made suitable for students and research workers, but the field is becoming so vast that one must be sympathetic.

A New Fossil Anthropoid Skull from South Africa

By Dr. R. Broom, F.R.S., Transvaal Museum, Pretoria

IT is nearly twelve years ago since Prof. R. A. Dart startled the world by the announcement of the discovery of a new type of fossil anthropoid found in a limestone cave at Taungs in Bechuanaland, South Africa. The specimen consists of most of the brain cast and the practically perfect face of a very young ape. The functional teeth are all of the milk set, though the first upper and lower molars have cut the gum but do not yet meet. Though the ape was only very young, Dart estimated the cranial capacity at more than 500 c.c., and considered that in an adult it might exceed 700 c.c. He believed that this little fossil ape is not very closely allied to either the chimpanzee or the gorilla, and that it is probably nearer to the ape from which man has been descended and thus to be practically the long sought for missing link.

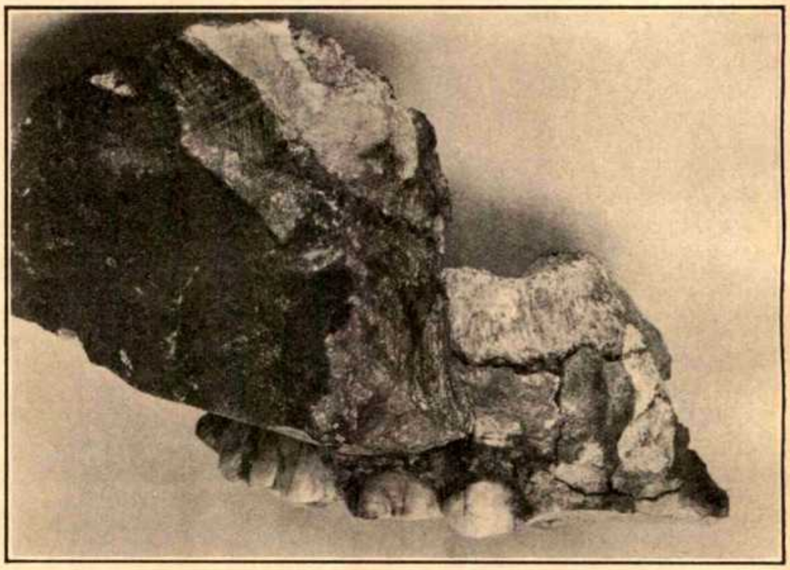

FIG. 2. Side view of right upper maxilla with the 2nd premolar and the 1st and 2nd molars. Parts of the roots of the canine and 1st premolar are shown. Slightly enlarged. Photograph by Mr. Herbert Lang.

Many European and American men of science considered that Dart had made a mistake, and that if he had had a series of young chimpanzee skulls for comparison he would have recognized that the Taungs ape is only a variety of chimpanzee. When after some years the lower jaw was detached from the upper and the crowns of the teeth could be examined fully, it was found that the milk teeth are not in the least like those of either the chimpanzee or gorilla, and that they agree entirely with those of man, though larger. In the gorilla and chimpanzee the first upper milk molars have each two cusps: in man and in *Australopithecus* there are three well-marked cusps in each. In the first lower milk molar of the gorilla there is only one large cusp; in the chimpanzee there is one large cusp and a second rudimentary cusp. In man and in *Australopithecus* there are four well-developed cusps.

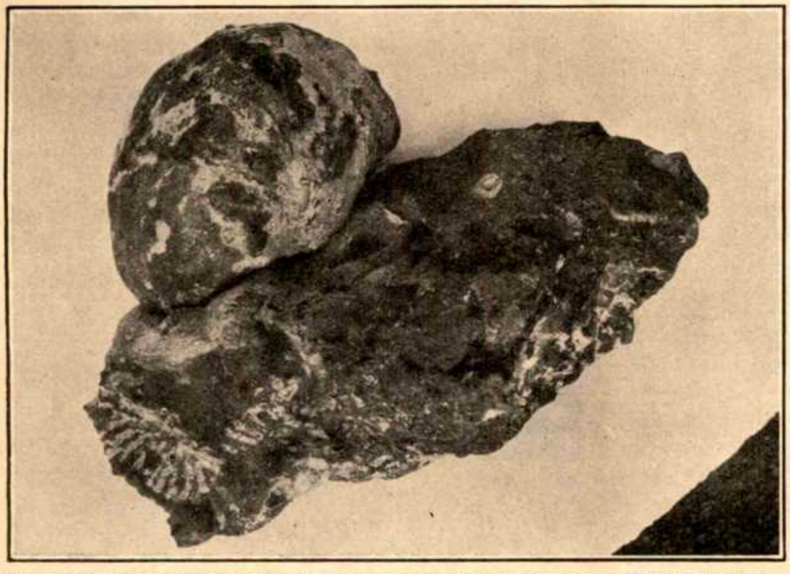

FIG. 1. Half side view of the brain cast resting on the imperfect base. The brow ridges are shown with parts of the frontal sinuses exposed. Part of the left cheek bone is also shown. About ½ natural size. Photograph by Mr. Herbert Lang.

I have constantly maintained since I first examined the skull in 1925 that Dart was essentially right in holding *Australopithecus* is not closely allied to either the gorilla or chimpanzee, and is on or near the line by which man has arisen.

I do not know what is at present the opinion in Europe as to where *Australopithecus* ought to be placed. Gregory of New York regards it as fairly near to the origin of the human line; and Romer of Harvard says it is "clearly not a chimpanzee or a gorilla". But the most important thing to do seemed to be to get an adult skull. For the last three months, I have been busy working on the bone breccia of the limestone caves of the Transvaal largely in the hope of getting either a new 'missing link' or a type of primitive man. I have so far found no trace of man, though I have discovered more than a dozen new species of fossil mammals, a number of which belong to new genera.

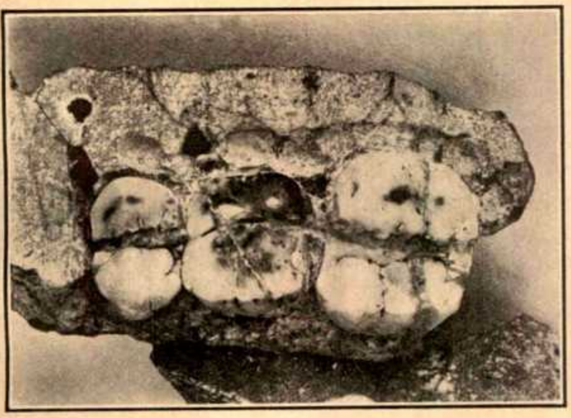

FIG. 3. Crowns of right upper 2nd premolar and 1st and 2nd molars. × about 4/3. Photograph by Mr. Herbert Lang.

Two weeks ago [Dr. Broom's covering letter is dated August 8.—Ed.], when visiting the caves at Sterkfontein near Krugersdorp, Mr. G. W. Barlow, the very understanding manager of the lime works there and on whom I had impressed the importance of keeping his eyes open for a Taungs ape, handed me the brain cast of what appeared to be a large anthropoid (Fig. 1). It had been blasted out of the side of the cave a couple of days before. A search for some hours failed to find any other part of the skull, but we found the cast of the top of the head in the cave wall. A more extensive search on the following day with a large party of workers resulted in the discovery of most of the base of the skull, with the upper part of the face (Fig. 2). In the same matrix was found the detached right maxilla with three teeth, and the third upper molar was also found, though detached. The lower part of the face had been removed before fossilization; and so far no mandible or lower teeth have been found, though parts may yet be discovered in a mass of crushed and broken bones near the side of the head. As the bones are very friable, no attempt has as yet been made to remove them from the much harder matrix.

Much of the cranial vault has been destroyed by the blast, but a large part of each parietal is preserved and a considerable part of the occiput. Unfortunately, the back of the brain cast is missing, and though the base of the skull is complete to the back of the foramen magnum, the contacts of the occipital fragment are lost.

The brain cast is perfect in its anterior two thirds. When complete it probably measured in length about 120 mm. and in breadth about 90 mm.; and the brain capacity was probably about 600 c.c. The skull probably measured from the glabella to the occiput about 145 mm., and the greatest parietal width was probably about 96 mm.

The brow ridges are moderately developed and there are fairly large frontal sinuses. The auditory meatus is 73 mm. behind the brow. It will be possible to make out much of the detailed structure of the base of the skull, but as yet no attempt has been made to clean it out as the bone is very friable and the investigation cannot be done in a hurry.

In the maxilla there are three well preserved teeth, the 2nd premolar and the 1st and 2nd molars (Fig. 3). The canine and 1st premolar are lost but the sockets are preserved. The canine has been relatively small. At its base it probably measured about 10 mm. by 8 mm. The 2nd premolar is somewhat worn. Its crown measured 11 mm. by 9 mm. Its pattern is well seen in Fig. 3.

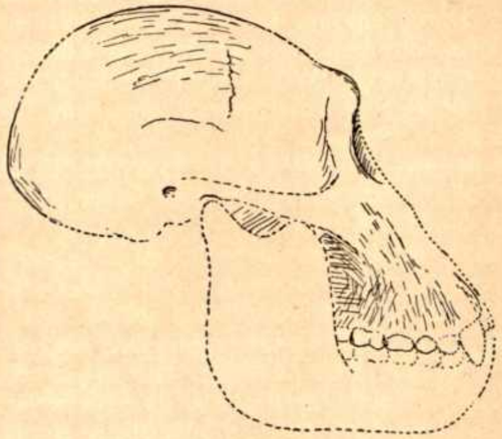

FIG. 4. Attempted restoration of skull of *Australopithecus transvaalensis* Broom. ½ natural size.

Sufficient of the cranium is preserved to show its shape with certainty. Most of the right maxilla is preserved, but it is not in contact with the upper part of the skull, and there is thus a little doubt as to the relations.

The 1st molar is moderately large. Antero-posteriorly it measures 12 mm. and transversely 13 mm. It is of the typical Dryopithecid pattern—four well-developed cusps with a little posterior ridge and a well-marked posterior fovea. The tooth agrees fairly closely with that of the first molar of *Dryopithecus rhenanus*. The 2nd molar is exceptionally large. It measures 14·5 mm. in antero-posterior length and is 16 mm. across. It has four large cusps with a well-marked posterior fovea. The 3rd molar has been detached from the bone but it is preserved in perfect condition and unworn. It has three well-developed cusps, but the hypocone is relatively small owing to the invasion of the large fovea. The tooth measures antero-posteriorly 13·7 mm. and transversely 15·5 mm. The crown in this unworn condition is extremely wrinkled.

The whole premolar and molar series measures 59 mm.

This newly-found primate probably agrees fairly closely with the Taungs ape, but the only parts that we can compare are the brain casts and the 1st upper molars. The brain cast of the new form is considerably wider, especially in the frontal region, and the molar teeth differ in a number of important details. Further, the associated animals found at Taungs are all different from those found at Sterkfontein. I think the Taungs deposit will probably prove to be Lower or Middle Pleistocene, while the Sterkfontein deposit is most probably Upper Pleistocene. I therefore think it advisable to place the new form in a distinct species, though provisionally it may be put in the same genus as the Taungs ape.

This discovery shows that we had in South Africa during Pleistocene times large non-forest living anthropoids—not very closely allied to either the chimpanzee or the gorilla but showing distinct relationships to the Miocene and especially to the Pliocene species of *Dryopithecus*. They also show a number of typical human characters not met with in any of the living anthropoids.

The Control of the Circulation of the Blood*

By Prof. R. J. S. McDowall

VARIATIONS IN THE ACTIVITY OF THE HEART

THE heart is not like an ordinary pump which sucks fluid from one tube and pushes it into another. The veins are so thin that any degree of suction would cause them to close. The heart is filled by the pressure of the blood which reaches it during the time it is relaxed, and adjusts the force of its stroke to the amount of blood in it at the beginning of contraction. The more blood reaching it, the more it pumps out, within limits. This is made possible by the fact that the force with which the heart contracts is increased if the heart muscle is stretched.

The heart can also change its rate. In the past it has been usual to describe the heart as being under two sets of controlling nerves, one the sympathetic, which when stimulated makes the heart go fast, and the other the vagus, which makes the heart go slower. Now we know that this is only part of the story. The evidence is almost complete that the heart is really under the control of two sets of reflexes which have this function. The difference between these statements is that the second involves an afferent pathway to the central nervous system, for the sympathetic and the vagus are constantly carrying down impulses to the heart, and if they are cut off the heart goes slow or fast as the case may be. In the case of the sympathetic, we do not know accurately as yet the exact source of the afferent impulses, but the fact that stimulation of any sensory nerves causes cardiac acceleration suggests that the source is stimulation from the outside world. This is not necessarily conscious, for it has been shown that a sound may accelerate the heart of a person who is asleep, but during waking hours the higher centres undoubtedly play a part in the acceleration. I shall refer to this further in relation to the vasomotor centre. In the case of the inhibitory impulses which slow the heart, the source of the afferent impulses is known. These arise from certain sensitive regions within the circulation itself. These are situated in the left side of the heart, the arch of the aorta and the carotid sinuses, which are small dilatations at the bifurcation of the common carotid artery in the neck.

When exercise is taken, two changes occur: the sympathetic accelerator impulses increase and in particular the vagus impulses are reduced. The evidence for this rests on the effect of exercise and other procedures on the heart rate before and after section of the vagi, and with and without the sympathetic. It has been shown, for example, that if the vagus nerves have been cut the increase of the heart rate is, during the exercise, not nearly so great as it was before they were cut. It is not possible for me to discuss here how the change is brought about, except to say that it is in part due to the action of the higher centres and to a rise of venous pressure. The increased temperature of the blood and adrenaline liberated by the suprarenal gland enhance the effect of the nervous changes.

---

* From the presidential address to Section I (Physiology) of the British Association, delivered at Blackpool on September 11.

What I want to emphasize is that the range of acceleration is determined by the degree of activity of the cardio-inhibitory reflexes: indeed, it has been recently shown in Belgium that the capability of dogs to withstand sustained activity is apparently enhanced by removal of the sympathetic. The extent to which the animals have then to rely on the reduction of vagus activity is thereby increased. This, of course, does not mean that the maximum effort for short periods is increased. To show this it is necessary to time the running of the animal over short distances. It has been shown that in athletes during mild exercise the cardiac output is increased with a trivial increase in cardiac rate—that is, the increase is chiefly produced by an increased output per beat. I shall, however, return to this point. Meantime I should like to leave you with the question: The heart increases its output; where does it get its blood ?

Experimentally it can be demonstrated that the vagus restraint of the heart is extremely variable—not only in different animals, but also in the same animal under different conditions, as may be seen if we block the vagi. For example, if we give an animal nitrogen to breathe, the normal vagus restraint can be shown to have disappeared. Or we can increase the restraint by previous sensory stimulation. This last experiment is of special interest, as it may give a clue as to how the normal vagus restraint is built up. We know that animals and human beings which take large amounts of exercise have slow hearts. How exactly this slow heart is produced is not yet clear. All we can say at the moment is that certain procedures such as sensory stimulation or asphyxia increase the heart rate, partly by reducing vagus activity, but that afterwards this reduction is followed by an increase in the activity of the vagus.

VARIATIONS IN THE CALIBRE OF THE BLOOD VESSELS

It may be taken as a general principle that in physical exercise the blood is distributed to the active tissues at the expense of the less active tissues. This local dilatation of vessels, combined with a rise in the general blood pressure which is the result of increased cardiac output and constriction of vessels in less active tissues, results in an enormous increase in blood flow through the active muscles.

The cause of the chemical dilatation has been a matter of considerable debate. It has been demonstrated that blood issuing from tetanized limbs has a vasodilator action. There are first to be considered the products of carbohydrate metabolism—carbon dioxide and lactic acid. Each of these has been observed to cause vasodilatation if applied in suitable concentrations to capillaries under the microscope. I emphasize the concentration, because larger concentrations have the opposite effect. It may be demonstrated also that, if the vessels of the hind limb of a chloralosed animal are perfused with the nerves intact and carbon dioxide is administered, the perfused vessels constrict because of the action of the carbon dioxide on the vasomotor centre, but the blood-pressure does not necessarily rise, presumably because there has been a compensatory dilatation of vessels in the rest of the animal. A number of workers, especially Fleisch, have demonstrated that vessels are sensitive to most minute changes of hydrogen ion concentration, even that which is produced by the addition of the normal amount of carbon dioxide to the blood, and personally I think that normally this is the most important factor concerned.

There is, however, evidence that certain substances of protein origin may be involved. Of these the most important is histamine. It has recently been shown by Anrep that the vasodilator substance which is liberated into the venous blood gives all the known biological reactions for histamine, and it is possible to demonstrate that extensive tetanization of muscles may produce a state which is a very similar one to histamine shock. There is at the same time a constriction of pulmonary vessels such as is produced by histamine. This liberation of histamine—if it be histamine—is of interest, as biochemists have reported that, compared with other tissues, muscles contain relatively little histamine. It is, however, somewhat doubtful if we are justified in considering that what happens during a severe artificial tetanus necessarily occurs in normal exercise.

The nervous dilatation is, judging from the work of Cannon and his associates, probably sympathetic. Here we see a dual function of the sympathetic, for its constrictor action is much better known. It has been known for some time that the sympathetic contained vasodilator fibres. In order to show the vasodilator fibres in the sympathetic, it is necessary to paralyse first the vasoconstrictor fibres with ergotoxine (Dale), or to use slow rates of stimulation. In this connexion it may be remarked that this slow rate of stimulation may be an imitation of what normally occurs, since presumably ordinary muscle contraction may give rise to similar stimuli.

Once the exercise has begun, it seems likely that local vasodilator reflexes, similar to Lovén reflexes, are set up by afferent impulses arising within the muscles themselves, possibly as a result of the mechanical and chemical changes which take place. The evidence is somewhat scanty, but it is impossible to ignore any longer the possibility of the existence of a nutrition reflex as suggested by Hess and supported more recently by Fleisch. By this is meant the fact that oxygen lack in a part sets up afferent impulses which result in reflex dilatation.

Capacity effects.—Now it has been shown by Krogh that when a muscle is active an enormous number of hitherto closed capillaries open up. This opening up of vessels previously closed necessitates the provision of blood, and as there is only a limited amount of blood in the body, it must be provided from other regions, otherwise the blood pressure would fall and the circulation through the tissues be reduced.

It is probable that practically all parts of the body, except possibly the voluntary muscles, the heart muscle and the brain, provide the blood necessary for the active muscles. It has been shown that any exercise, actual or even contemplated, causes vasoconstriction. Constriction of the spleen and of the intestine in animals has been observed. In man it has been shown that the vessels of the skin constrict under any emotional stress or even anticipated activity.

In regard to the sympathetic constriction of the vessels, we are in the same difficulty as we were in relation to the sympathetic acceleration of the heart. We do not know how the actual nerve impulses which originate the constriction arise. For convenience we say that they begin in the higher centres of the brain. It is, however, probably preferable, it seems to me, to consider that it is a sensory stimulation from the outside world, which is the point in time determining the psychical reaction which results in motor movement. Certainly we know that stimulation of a sensory nerve causes generalized vasoconstriction and commonly a rise of blood pressure, and that similar changes but of lesser degree may be recorded in a sleeping man.

It has been usual to ascribe the shutting down of the blood vessels solely to sympathetic activity, just as it was usual to ascribe cardiac acceleration solely to such action. In the case of the heart we have clear evidence that the reduction of the vagus restraint is just as important by increasing the range of cardiac activity and creating a cardiac reserve. It has now become evident that there probably exists an exactly parallel mechanism which increases the range of vascular activity and similarly enhances the reserve.

MAINTENANCE OF THE VASCULAR RESERVE

Just as we have the restraint of the heart by the vagus, which determines the range of cardiac acceleration, so we have in relation to the blood vessels a set of reflexes which determines the magnitude of the vasoconstriction of the blood vessels; that is, they maintain the vessels of the body generally in an actively dilated state. The afferent impulses which are concerned in these reflexes have an exactly similar origin to those responsible for the vagus restraint of the heart. They arise from the cardio-aortic region and the carotid sinuses, and pass up the medulla by the aortic and carotid depressor nerves. Like the cardio-depressor reflexes, the vascular-depressor reflexes are operated by the intravascular pressure in these regions.

It has been generally assumed that the primary function of this control of the vessels is to maintain the arterial pressure at a constant level, and this is quite reasonable, for a constant mean pressure is desirable to maintain a steady flow of fluid at rest from the capillaries to the tissues.

More recently it has become evident that these reflexes may have another and possibly more important function. Several facts led to this suggestion: (1) in physical exercise or mental stress, the blood pressure, like the heart rate, does rise in spite of the reflexes; (2) the response of blood pressure to posture may be normal if the reflexes are destroyed—a fact which shows that the maintenance of mean pressure is not wholly dependent on the reflexes; (3) as in the case of the vagus, different animals, or even the same animals in slightly different circumstances, show great variability in the activity of the reflexes—often it is possible to throw the reflexes out of action without affecting the blood pressure materially; and (4), as might almost be anticipated, the conditions which reduce the activity of the vagus also reduce the activity of the depressor reflexes.

Now since in exercise the venous pressure is increased and, if the stress of the occasion is sufficient, adrenaline is secreted, we may consider what happens to the circulation when the vaso-depressor reflexes are thrown out of action. As I have said, there is a rise of arterial pressure and a generalized constriction of the vessels. It has become usual to consider that this rise of arterial pressure is the result of an increased peripheral resistance to the flow of blood from the arteries. Were this wholly true, we should expect to find that there is a reduced flow of blood to the veins. If the animal, however, is in good condition, the reverse is the case: there is an increased flow to the veins. It is as if there were at the periphery a sponge-like reservoir which, when it is contracted, drives its store of blood into the veins.

When the depressor reflexes are cut off, the reverse, however, does not necessarily occur experimentally. An increased flow into the veins does not necessarily result in a rise of venous pressure, because at the same time the heart is stimulated and the increased pressure is rapidly dealt with. It can, as might be expected, be shown at the same time that there is an increased output of the heart. It is not possible to measure the output of the heart by the cardiometer method without there being some degree of shock or permanent increased capacity of the circulation from the absorption of toxic products. As a result, the increased cardiac activity more than balances any increased flow in the veins, and the venous pressure may actually fall. Commonly it remains unchanged in such experiments. However, if the animal is not subjected to any severe operative procedure, a small rise of venous pressure is the rule. Perhaps I should say that several workers using the Fick method have shown an enormously increased output of the heart when the impulses from the carotid sinus are cut off.

What we can imagine happens in exercise or emotion is, then, that just as the vagus restraint of the heart becomes reduced, so also the depressor restraint of the vessels becomes reduced, more blood is thrown into the circulation and is dealt with by the heart, which at the same time increases both its rate and its output per beat. It is to be anticipated that we shall eventually get evidence that the extent of the activity of the vasodilator reflexes varies in different animals just as the activity of the vagus varies.

The sympathetic and adrenaline.—All the mechanisms which I have described are probably still further enhanced by the vasoconstrictor action of the sympathetic and the action of adrenaline, which is apparently secreted whenever the emotional stress of the occasion is sufficient. Adrenaline in physiological amounts constricts the vessels of the skin and splanchnic region and dilates the vessels of the muscles. Here I should like to emphasize that probably the physiological dose of adrenaline is minute, and may even be insufficient to raise the blood pressure. Certainly the dilatation of muscle vessels is not a result of the rise of blood pressure which may occur, for it can be shown that the dilatation occurs with doses which do not raise the arterial blood pressure. An increased blood flow through the limbs can also be shown to be brought about by doses which do not raise the blood pressure. In such circumstances the constriction just counterbalances the dilatation. Why adrenaline should constrict some blood vessels and dilate others is a major problem in the study of the circulation. Since so far as we know the vessels themselves have the same structure in different parts of the body, we must assume that the difference is due to the different environment. I had hoped by this time to have obtained some definite evidence on this point, but so far the experiments have not been completely successful.

It is interesting to observe the effect of adrenaline on the depressor reflexes. If the hormone is injected, it is found that some minutes afterwards, even after the usual rise of blood pressure has passed off, it is not possible to affect the heart by a degree of stimulation of the vagus which was previously effective, and at the same time the effects of cutting off the impulses from the carotid sinus are markedly reduced or completely abolished. This, of course, is exactly what would be expected if adrenaline were secreted in the same circumstances in which the action of the depressor reflexes and the vagus are reduced, as in exercise.

A further corroboration of this somewhat new view of the function of the vasodilator reflexes comes from a study of the effect of exercise and of emotion on man. It is well known that when a man takes exercise on a stationary bicycle his systolic blood pressure goes up, but falls even below normal the moment the exercise stops. This fall has been explained by Cotton, Slade and Lewis as due to the accumulation of blood in the vessels of the dilated muscles, but from what I have said in relation to the diminution of the peripheral resistance in muscle, it is evident that the fall is in part due to a diminution of this resistance. Now if a careful comparison be made of the psychical effect of intended exercise and that of exercise, it has been found by Gillespie that there is no difference. In other words, the rise of arterial pressure in exercise is the result of psychical changes.

If exercise could be taken without psychical zest being involved, we might expect the blood pressure to fall. This, indeed, has been found to occur in the horse. In man, too, it has been found that if the exercise is slight, although the systolic arterial pressure rises, the diastolic pressure falls. This means that more blood is being pumped out of the heart per beat, but that blood escapes from the arteries more rapidly than normally before the next systole. In other words, from psychical causes alone there is a rise of arterial pressure from an increased cardiac output per beat, which can only be the result of more blood reaching the heart. In emotion, too, it is known that the systolic pressure rather than the diastolic rises. Since we have seen from the experiments of Mosso with the plethysmograph, of Barcroft on the exteriorized spleen and of Florey and Florey on the exteriorized colon, that generalized vasoconstriction is an accompaniment of psychical effort, we must assume that the increased output of the heart is in part, if not wholly, the result of the vasoconstriction which calls into use the reserves of blood, and thus the circulation is maintained in spite of the greatly increased capacity of the active muscles.

Chemistry and the Modern State*

By Prof. J. C. Philip, O.B.E., F.R.S.

IN relation to those essential activities of any society which is intellectually alive—the pursuit of new learning and the cultivation of the spirit of inquiry—chemistry is in the forefront. For the promotion of natural knowledge and the increase of our understanding of the universe, the chemist has laboured with extraordinary success, both in his own fields and in those borderlands where chemistry marches with other sciences. It is perhaps worth while glancing at one or two of the chief avenues in the region of chemical knowledge opened up by such fundamental research.

While our knowledge of atomic structure is to be credited mainly to the work of physicists, the chemist's technique has revealed the molecular architecture of the most complex natural products, and on the basis of this knowledge the same materials can be synthesized in the laboratory. One has only to think of the sugars, the alkaloids, the anthocyanins, to realize the astounding results which have been achieved in this field of investigation, while such elusive substances as the vitamins and the sex hormones are rapidly yielding their secrets to the strategy of the organic chemist.

Take, again, that region in the scale of size which lies between the molecule and the visible particle—the colloid region—the "world of neglected dimensions" as it was once described. In this region, as the physical chemist has shown, the relatively great extent of surface is marked by quite special behaviour, and the labile systems encountered exhibit peculiar characteristics—characteristics which are highly significant for the understanding of physico-chemical changes in the living organism. Our knowledge of this field of surface chemistry is still extending rapidly.

Once more, think of the tracking down of the factors which affect the rate of chemical change, and the elucidation of the mechanism of their operation: a little moisture, a speck of dust, a trace of acid, a roughened surface, a ray of light, a rise of temperature—any of these may have a notable influence on the rate of a reaction. The physical chemist has been remarkably successful in unravelling the role of these various factors and in interpreting their significance. It is in such a field as this—the field of kinetics and catalysis—that the progress of chemical science from the qualitative and descriptive way of treating phenomena to the rational and quantitative has been particularly marked.

These are only one or two of the directions in which the pioneering work of the chemist has opened the way to a fuller knowledge of Nature, especially in the more delicate aspects of her balance and her transformations. In the pursuit of natural knowledge for its own sake, the chemist has indeed travelled far, and his exploration has yielded an abundant harvest of discovery. For the pioneer himself it is an adventure, and original research may provide thrilling experiences. All this, however, is far from the common ways of men, and the investigator in the field of pure chemistry moves in a region mostly inaccessible to ordinary folk, and he speaks an unintelligible language, as indeed is true of specialists in other sciences. The so-called 'jargon' of science, inevitable as it is to some extent, presents a real difficulty in the transmission of knowledge and ideas from the specialist to the average educated man, but it should not be forgotten that other specialists besides scientific workers have a jargon of their own: to wit, lawyers, financiers, and even sportsmen.

It has been maintained that the pursuit of learning for its own sake is a selfish occupation; that knowledge should be a means to life, not an end in itself; that knowledge is of value only in so far as it leads to action, directly or indirectly. With this view I have much sympathy; but it has become abundantly clear, so far at least as knowledge and discovery in the realm of pure chemistry are concerned, that we must take a very long view indeed in assessing their practical value. Again and again in the history of the science observations and discoveries have been made, which at the time were of purely scientific interest but later received important practical applications. The laboratory curiosities of a former generation, such as aluminium and tungsten, have become the industrial commonplaces of the present.

The application of exact methods of measuring density revealed the presence of a new gas in the atmosphere—a discovery of purely scientific interest in the first place—which has led to a whole train of remarkable consequences, from a drastic revision of our ideas about the elements to the widespread development of illuminated signs. Just one hundred years ago, at the Bristol meeting of the British Association in 1836, Edmund Davy announced the discovery of a "new gaseous bicarburet of hydrogen", now familiar as acetylene. Decades passed, however, before the novel gas acquired any practical significance, and indeed it was not until 1892, when a large-scale method for producing calcium carbide was discovered, that acetylene became of industrial importance. Since then its applications have gone ahead rapidly, and its uses in illumination, in welding, in metal-cutting, and in the synthetic production of organic chemicals are widely known. In view of these lessons from the history of chemical science, one hesitates to apply the epithet 'useless' to any specific observation or discovery, however 'academic'. Reflection indeed suggests that the really big changes in the material conditions of human life have generally had their origin in a search for knowledge on its own account.

---

* From the presidential address entitled "The Training of the Chemist for the Service of the Community" to Section B (Chemistry) of the British Association, delivered at Blackpool on September 10.

There is, however, much more to be said on this matter of fundamental or academic research. A solution of the most practical of chemical problems on rational and scientific lines is possible only because of our accumulated knowledge of natural phenomena and natural laws. It is only against the background provided by the pure research of yesterday that the technical problems of to-day can be viewed in their proper setting and tackled with a reasonable prospect of success. I would submit, therefore, that work in pure science, remote as it generally is from the practical issues of the moment, is building up a real reserve of knowledge and technique on which future generations of practical workers will be able to draw.

Apart from the chemists who are engaged, mostly in our universities and colleges, but to some extent also in the larger research institutes, in the general task of extending the boundaries of knowledge, there are many more who are carrying on what may be called 'directed' research. Their work aims at the solution of some specific problem, concerned, it may be, with the improvement of an industrial process, the elimination of waste, the safeguarding of health, the utilization of by-products, the synthesis of antidotes. More definitely, and by way of example, the object may be to discover a fast blue dye, to purify a water supply, to find a rustless steel, to produce petrol from coal, to isolate a vitamin, to make a non-inflammable film or a creaseless cotton fabric. The general public, however dubious about pure research, would probably admit that the satisfactory solution of any one of these problems would be of service to the community ; but it must be emphasized once more that the chemist can do these things only by virtue of his inheritance of knowledge and technique. The attack on such problems, to have a reasonable chance of success, must be organized on the basis of what is already known and what has already been achieved ; nay, more, one has abundant ground for belief that the attack, so organized, is bound to succeed, even though it may be 'in the long run'.

In the last twenty years, the amount of directed chemical research in Great Britain has increased enormously. Industries of the most varied description have begun to realize the potential value of the trained chemist in solving their special problems and putting their manufacturing processes on a more rational basis. In this general movement the State, through the Department of Scientific and Industrial Research, has taken a prominent part by fostering research associations. The work of these organizations—such as those dealing with rubber ; with paint, colour and varnish ; with cotton or wool ; with non-ferrous metals ; with sugar confectionery—is in many cases largely chemical or physico-chemical in character. The research associations have not only shown how general problems affecting an industry as a whole can be solved by joint research efforts, but also their existence and activities have induced a notable degree of 'research-mindedness' in the individual associated firms. Financially, the work is based on co-operation between the State and industry, on the principle that the State helps those who help themselves.

The State itself has founded a number of organizations for the study of chemical problems of national importance, and has thus formally recognized the significance of directed research for the community. The work carried out at the Chemical Research Laboratory, Teddington, has included the study of synthetic resins and low-temperature tars and the exploration of chemical reactions occurring under high pressure, as well as research on metal corrosion, chemotherapy and water softeners.

Fuel and food are two notable cases in which State-aided investigation is being carried out, and problems connected on one hand with pulverized and colloidal fuel or the low-temperature carbonization of coal, and on the other with the storage of fruit or the preservation of fish and meat, are being intensively studied at appropriate centres. Reference might be made also to the work of the Building Research Station, where, amongst other matters, the factors determining the weathering qualities of stone are being studied. Other experts than chemists are naturally concerned in the investigation of these problems, but the chemical and physico-chemical aspects are frequently the predominating ones.

Again, the serious question of river pollution has been taken in hand with State help, and some years ago a chemical and biological survey of the River Tees was set on foot, the Tees being chosen for investigation because of the great variety of factory effluents discharged into it both in tidal and non-tidal reaches. Some of the newer industrial developments in Britain are presenting important problems in this direction. It has been estimated, for example, that if the waste waters from all the beet sugar factories in the country were discharged into our streams, they would cause as much pollution as untreated sewage from a population of four or five millions. The effluents from dairies and factories making milk products present a similar problem. Thanks, however, to research activity, largely at the instance of the Water Pollution Research Board, the disposal or purification of these and other trade effluents is being effectively achieved.

The question of river purification demands for satisfactory handling, as already indicated, the collaboration of other scientists with the chemist, and indeed the attack on many such problems, especially those affecting the health of the community, is likely to be successful only by the co-operation of teams of scientific workers from different fields. Smoke and fog, which not only present the scientific worker with interesting phenomena but constitute also a social and industrial problem of vital importance, concern the physicist, the physical chemist, the analyst, the fuel engineer and the meteorologist, and it is only when the knowledge and experience of these workers are pooled that there is any hope of interpreting the phenomena and solving the problem. Again, recent developments in cancer research make it clear that apart from the pathologist, who is mainly concerned, the chemist has a very definite contribution to make to our knowledge of this baffling disease. Some of the most fruitful scientific investigation, indeed, is cooperative in character.

Research, whether fundamental or directed, is by no means the only outlet for the chemist's knowledge and craftsmanship. The works control of chemical processes, the examination of factory products, the safeguarding of the purity of food, and the supervision of water supplies and sanitation, are examples of other activities of a more routine character in which large numbers of chemists are engaged. These are, so to speak, the general practitioners of the chemical profession, and their contribution to the smooth running of industry and to healthy living is far greater than most people suppose. I have myself been surprised, in a recent survey of the present occupations of my former students, by the extraordinary variety of the work in which chemically trained men may be engaged. This survey shows that photographic emulsions, beer, high-speed steel, printing ink, linoleum, dental cream, gramophone records, bank notes, and mineral waters, are a few of the materials with the production of which the chemist is concerned, either in the laboratory or the works. It is true to say that in the industry of the country the chemist is ubiquitous.

I have spoken of the 'chemical profession', and the phrase was used deliberately. A profession is a vocation demanding high educational and technical qualifications, and it connotes also the body of those who by virtue of their qualifications are able to serve the needs and welfare of society in some particular field. On all these counts, chemistry should have a place beside medicine, law and engineering. That the public is so slow in recognizing this claim may be due to the fact that the chemical profession is not yet unified to the same extent as the others mentioned ; but it is due also to a lack of realization of the fundamental and widespread character of the service which the chemist renders to the community.

A just estimate of the chemist's function is almost impossible for those who associate him chiefly with explosives and poison gas, and regard him as a particularly devilish kind of scientist. Such a picture is hopelessly out of relation with the facts. It is, of course, true that chemists have produced dangerous and poisonous substances, but most of these were discovered originally in the general quest for knowledge, and many have legitimate and valuable applications ; their use for destructive purposes is a perversion. Phosgene, for example, one of the so-called poison gases, was discovered more than a hundred years ago, and is an important material at the intermediate stage in the manufacture of certain dyestuffs. Nitrates, which are the basis for the manufacture of most explosives, play a prominent role as fertilizers in agriculture, and explosives themselves are indispensable in mining operations.

The truth is that the employment for other than beneficial ends of the substances discovered by the chemist is due, not to his especial wickedness, but to the weakness and backwardness of the human spirit. Like other scientists, the chemist normally has a constructive point of view, and he cannot but deplore the fact that, as Sir Alfred Ewing once said : "The command of Nature has been put into man's hands before he knows how to command himself". I think I speak for the vast majority of my fellow-chemists in saying that we dislike intensely the present world-wide prostitution of knowledge and skill to destructive ends. The sooner this is eliminated, and the less call there is for lethal and devastating materials, the greater will be our satisfaction.

There are, indeed, welcome signs that scientific workers are increasingly impatient at the extent to which their knowledge is made to serve inhuman ends. The possibilities before humanity have been fairly set out by a recent historian, H. A. L. Fisher: "The developing miracle of science is at our disposal to use or to abuse, to make or to mar. With science we may lay civilization in ruins, or enter into a period of plenty and well-being, the like of which has never been experienced by mankind". To the clearing of this conflicting situation, the scientific worker has not always made the constructive contribution which he might have done: he has been content to adopt an objective and detached attitude, suggesting sometimes complete indifference to the wider human issues at stake, assenting too readily to the misuse of his knowledge and skill. Impelled by patriotic motives, most men of science have put themselves freely at the disposal of the State in time of need, but many are hesitating to admit that patriotism must always override considerations of humanity. Whatever be our individual attitude in this matter, it is time for chemists and scientists in general to throw their weight into the scale against the tendencies which are dragging science and civilization down and debasing our heritage of intellectual and spiritual values.

Obituary

Prof. A. P. Karpinsky

PROF. ALEXANDER PETROVICH KARPINSKY, the greatest of Soviet geologists, president of the Academy of Sciences of the U.S.S.R., of which he had been a member for fifty years, died on July 15 in his ninetieth year. He was a foreign member of many learned bodies; the Geological Society of London elected him a foreign member in 1901 and awarded him the Wollaston Medal in 1916.

An entire epoch in the history of Russian geology, following that of Murchison (the forties of the past century), is connected with Karpinsky's name. Karpinsky compiled a new, much more detailed geological map of the European part of the U.S.S.R. and the Urals. This map was the ground-work of the Russian geological service, of which he was one of the creators, and which was then known as the Geological Committee. Being during many years practically the head and leader of that institution, the staff of which was mainly composed of his pupils, Karpinsky was the creator of the new stratigraphy of Russia. This, however, does not exhaust the significance of Karpinsky's work in the history of geology. He was the last of those geologists who embraced the whole of geological science, working with equal skill in every branch of it.

Karpinsky's personal field-work in stratigraphy concerned all the systems and various regions of the European part of the U.S.S.R., but mainly the Urals; he was the first to solve the enigma of the eastern slope of the latter. His contributions which demonstrated the tectonic structure of the Russian platform were only completed, never reconstructed by later explorers, and were of immense value. He first established the regularity of movements of the earth's crust. Only much later did his ideas receive wider development in the theory of geosynclines.

Karpinsky's palæontological studies are of no less importance. Of his works on invertebrates the most remarkable are those concerning the palæozoic ammonoids. He was one of the first to apply the ontogenetic method, and not to single forms, but to a whole fauna. This led to most important conclusions both zoological and geological (he proved the evolution of the Artinskian fauna *in situ*, whereas it was considered immigrant). A most remarkable study is that on *Helicoprion*, a primitive shark, to the study of which he applied the histological method with brilliant results.

Particular attention may be directed to his monograph on Trochilisks—tiny Devonian algæ. To write this monograph, Karpinsky had to become a botanist. It is curious to note that in a controversy with botanists who did not share Karpinsky's opinion of these fossils, the victory went to Karpinsky. In petrology, besides special studies by which began his scientific activity, it is worth mentioning that he was the first in Russia to introduce the microscope in the study of petrographic slides.

From the very beginning of his scientific activity, Karpinsky was interested in deposits of useful minerals. He forecast the discovery of salt at Bakhmut, he advanced the view that petroleum deposits exist in the Urals; this has been brilliantly confirmed by recent prospecting for petroleum at Ishimbaievo, exactly in the Artinskian deposits established by Karpinsky, as well as by that at Krasnokamsk in the Middle Carboniferous. Karpinsky was particularly interested in the problem of the origin of platinum deposits; he studied some iron deposits and so on. He may be justly called the founder of the practical geology of the Urals.

Karpinsky continued working to his last days, and on his death bed he asked for paper to write down a new idea. In Karpinsky we lose not only the greatest Soviet scientist, but also an excellent man and citizen. Despite his high position, he never ceased to be modest, simple, accessible to everyone, especially to young students, at whose disposal he readily put his knowledge and experience. Injustice and untruth alone aroused his anger, and he frequently expressed his sympathy with the Soviet Government, which he used to call "the most just in the world".

A. BORISSIAK.

Prof. P. H. Stroobant

WE record with regret the death at the age of sixty-eight years, after a painful illness, of Prof. Paul Henri Stroobant, honorary director of the Royal Observatory of Belgium at Uccle. Prof. Stroobant had only recently retired from the directorship of the Observatory which, in May 1935, had celebrated the hundredth anniversary of its foundation. On the occasion of the centenary celebrations, which were honoured by the presence of King Leopold and attended by many foreign delegates, the new equipment of the Observatory was open to inspection. This equipment includes an elaborate Ascania meridian circle of 19 cm. aperture; a Cooke-Zeiss equatorial of 45 cm. aperture and 7 m. focal length, with micrometer; a double Zeiss astrograph, each telescope having quadruplet lenses of 40 cm. aperture and 2 m. focal length, covering a field of 72 square degrees; a Zeiss astrographic triplet of 30 cm. aperture and 1·5 m. focal length, covering a field of 81 square degrees; a 7° objective prism; a Zeiss reflector of 100 cm. aperture, equipped with two spectrographs; and also comparators and measuring machines. The modernization and reorganization of the Observatory was Prof. Stroobant's chief work as director, to which post he was appointed on May 1, 1925. He had previously been, since 1904, professor of astronomy in the University of Brussels.

Prof. Stroobant's astronomical work included the study of the personal equation in the observation of star transits; dynamical investigations on the planets and their satellites and, in particular, on the system of Saturn; researches on the distribution and number of the asteroids; investigations of the motions of the helium stars and of the solar motion. He was the first to establish that the apex of the solar motion and the velocity of the sun, with respect to the near stars, varies in a systematic manner with the spectral type of the stars. A volume entitled "Les Observatoires Astronomiques et les Astronomes", compiled in 1907 by Prof. Stroobant with the assistance of some of the staff of the Uccle Observatory, is a valuable reference work. A revised edition was published in 1931 under the auspices of the International Astronomical Union.

Prof. Stroobant was a *correspondant* of the Paris Academy of Sciences, of the Bureau des Longitudes, and of the Institut de Coïmbra. He was an associate of the Royal Astronomical Society, president of the Belgian National Committee of Astronomy and president of the Commission on Bibliography of the International Astronomical Union.

Dr. Edward Weston

BY the death of Dr. Edward Weston on August 20, the electrical industry loses one of its greatest pioneers. Born in 1850, on the border line between England and Wales, he went to the United States when fifteen years old and devoted his energies to studying the action of existing direct current dynamos and making improvements on them. If not the first, he was one of the first to realize the necessity of laminating the iron in the armature of a dynamo so as to obviate the heavy losses that otherwise occurred owing to the eddy currents induced by the alternating magnetic flux. Edison also worked on this problem, and the efficiency of the dynamo was soon raised from 50 to 90 per cent.

As a working method for the realization of the international volt, the Weston cadmium cell is used. At 20° C. its electromotive force is 1·0183 international volts. The researches made by Sir Frank Smith on this cell, and the modifications in the materials used to which these researches led, have made the Weston cell most trustworthy for the accurate measurement of voltages.

To electrical engineers, Dr. Weston's name is a household word in connexion with moving coil ammeters, voltmeters and wattmeters. The law governing a coil moving in a permanent magnetic field was used by Kelvin on his siphon recorders and by D'Arsonval in his galvanometer. In 1888, Weston, using this principle, developed and produced the first moving coil ammeters and voltmeters. Devices are now used by makers in all parts of the world for measuring amperes, volts and watts which use the essential principles of the original Weston instruments. In the original Weston D.C. ammeter, the coil is pivoted and is controlled by spiral springs which carry the current, but unlike the D'Arsonval galvanometer a pointer is substituted for the mirror. The ammeter can be converted into a voltmeter by using it in conjunction with a high resistance and into an ammeter for measuring large currents by shunting it with a low resistance.

Dr. Weston was the first to employ bakelite, so widely used to-day, on a commercial scale. Amongst his many inventions are a compensated thermocouple instrument for high-frequency A.C. measurements, the rectifier bridge for A.C. measurements and the first commercially practical dry disk photoelectric cell.

Dr. Weston was a past president of the American Institute of Electrical Engineers, and received many honours from learned societies. In 1933 he was awarded the Lamme medal of the Institute for his achievements in the development of electrical apparatus, "especially in connexion with precision measuring instruments". At the time of his death he was a director of the Weston Electric Instrument Corporation and the Weston Electrical Instrument Co. Ltd., at Surbiton. He is survived by his son, Mr. E. F. Weston, the president of the American company.

A. R.

WE regret to announce the following deaths:

Dr. W. H. Harrison, formerly Imperial agricultural research chemist for the Government of India, lately acting agricultural adviser, on August 18, aged fifty-nine years.

Prof. K. K. Mathur, honorary professor of geology in the Benares Hindu University, and principal of the College of Science, Benares, on July 18.

News and Views

British Association Meetings

THE Blackpool meeting of the British Association closed on Wednesday, September 16, with the assembly of the general committee, when research committees were appointed and resolutions were passed gratefully acknowledging the obligations of the Association to the Mayor and Corporation for their hospitality and the ways in which they had contributed to the work and entertainment of the Association at Blackpool. The meeting has been notable in several aspects, and one which is unique of its kind was the opening of the famous autumn illuminations on Saturday, September 12, when Sir Josiah Stamp, president of the Association, switched on from a train the 300,000 coloured electric lights on pylons and archways which illuminated the whole length of the promenade. The day had been spent by a large party which travelled by special train to Furness Abbey, Windermere, Rydal Water and Grasmere; and upon the return journey the train was stopped at Oxenholme so that Sir Josiah could speak from his carriage to the people of Blackpool before he pressed the button which started the illumination of the five miles of the promenade. Sir Oliver Lodge, who was given an enthusiastic welcome at the opening meeting, when he expressed the thanks of the Association to Sir Josiah Stamp for his presidential address, attended a few other meetings before he left on Monday. His presence at Blackpool was much appreciated not only by his scientific friends but also by the people of Blackpool.

NEXT year's meeting is to be held at Nottingham under the presidency of Sir Edward Poulton. The general officers remain as this year; namely, general treasurer, Prof. P. G. H. Boswell, and general secretaries, Mr. F. T. Brooks and Prof. Allan Ferguson. The new members of Council are: Dr. F. W. Aston, Prof. F. Debenham, Prof. T. G. Hill, Mr. W. Campbell Smith, and Mr. J. S. Wilson. The meeting in 1938 will be held at Cambridge, on August 17–24. In January of the same year, it is proposed to send a limited party of the Association to India, when a joint session will be held with the Indian Science Congress, which will then be celebrating its silver jubilee. The 1939 meeting will be held in Dundee. The question of a meeting in Australia is still under consideration; but it will probably not be held there until 1942, as it has been found that 1940, originally suggested, is inappropriate on account of several important international congresses having been fixed for that year.

Sir Edward Poulton, F.R.S.

THE election of Sir Edward B. Poulton to be president of the British Association for 1937 will cause great satisfaction, and is particularly apt in connexion with the renewed interest in Darwinism, and more especially in natural selection. This year's meeting has shown that there is a strong revival of belief in the efficacy of natural selection, and the presidential address to Section D (Zoology), and subsequent papers, demonstrated how much evidence is flowing along different lines to support the theory. The presentation to the world of Mendel's particulate theory of heredity in 1866 resulted in enthusiastic acceptance of the new doctrine and the belief that this process supplied the obvious means of evolution which would finally dispose of the less easily proved theory of natural selection. From this view, Sir Edward vigorously dissociated himself; but so prevailing was it that in the presidential address to the Association in 1913, Sir Oliver Lodge stated that not only was it not true that Nature does not make leaps, but that it was doubtful whether she ever does anything else. Now that the early conception of advance by large sudden changes has been so greatly fined down by the discovery of modifying factors, the two schools will be found to be less antagonistic. No one will rejoice in the reconciliation more than Sir Edward, himself eager to welcome and examine any new ideas on evolution, but always ready to hold the fort against new-comers with blaring trumpets acclaimed as the heralds of a new order.

SIR EDWARD POULTON is widely known for his exposition of the theory of natural selection as accounting for the colours of animals, particularly of insects; he has long been recognized as the chief authority on Darwinism in Great Britain. An Oxford man, having studied under Rolleston, he early distinguished himself as a morphologist; he was a vigorous supporter of Weismann's theory and took a practical part in making his views on the continuity of germ-plasm better known to the English-speaking public. But he became particularly interested in the problem of the colours of animals, and in his classical book, "The Colours of Animals", laid the foundations of his life's work. One general scheme was devised to cover all the manifestations of colour in animals, whether aggressive, protective, or for sexual attraction. The explanations by Bates and Müller of resemblances in colour between insects far removed in taxonomy found their keenest advocate in Poulton, who during forty years in the Hopeian chair of zoology at Oxford has been responsible for the accumulation of a mass of evidence for which no explanation has yet been put forward which covers so many points as does natural selection. Always ready to help in any work that would forward the study of evolution, he has consistently lectured and written as a supporter of Darwin's original views, as evidenced by his presidential addresses to the Linnean and Royal Entomological Societies, and to the zoological section of the British Association, which he has regularly attended since 1881.

Discovery of a New Fossil Anthropoid in South Africa

IN another column of this issue of NATURE (p. 486) there appears a communication from Dr. R. Broom, of the Transvaal Museum, Pretoria, in which he records the circumstances of discovery in July last of the skull of a new type of fossil anthropoid in South Africa, and goes on to give a preliminary report on the more striking and significant anatomical characters of his find, so far as these are patent at this early stage of examination. The specimen, as was almost inevitably the consequence of its discovery in the course of blasting operations, is fragmentary; but fortunately for the student of the palæontology of man and the anthropoids, those parts which have been found, especially the teeth and the forward parts of the brain cast, are among the most significant for determining the relation of the new fossil to previously known forms. Further—and this is a matter of considerable moment—it is at once apparent that not only do these fragments belong to a new type of anthropoid, but also the teeth are those of an adult individual. Hence, as Dr. Broom points out, his find confirms the interpretation which has been placed upon Prof. Dart's Taungs skull, which is infantile, and establishes it by the side of this new and related specimen from the Sterkfontein caves, as "not closely allied to either gorilla or chimpanzee", but "on or near the line by which man has arisen". Dr. Broom, however, considers that he is justified in regarding his new form as differing specifically from *Australopithecus*, while it is probably later, belonging to the Upper Pleistocene. The further implication of his discovery is indicated when, referring to the resemblance in the teeth to those of *Dryopithecus rhenanus*, he emphasizes the fact that a South African Pleistocene form, showing "a number of typical human characters, not met with in any of the living anthropoids", stands in distinct relationship to the Pliocene fossil apes and especially to the Pliocene *Dryopithecus* of Europe, which some palæontologists have regarded as one of the most important links in the chain of relationship between the fossil apes of Europe, Egypt and Northern India and the earliest form of man.

Science and Social Values

TIME and time again in these columns, reference has been made to the fact that men of science as a whole have, in the past, paid little attention to the social consequences of their investigations and discoveries, with the result that science has been widely blamed for the present-day world-wide unrest. While there is still a body of opinion that scientific workers should disclaim all responsibility for the use to which their discoveries are put, there is a growing feeling that men of science should take a more active part in public affairs. Sir Josiah Stamp, in his presidential address on September 9 to the British Association, referred to this topic, and went on to suggest that biological and social investigations should be given more attention than they are at present receiving. On September 10, Prof. J. C. Philip, in his presidential address to Section B (Chemistry) of the Association, part of which is printed in this issue of NATURE (see p. 492), roundly attacked those who find nothing in chemical science but explosives and poison gas, showing clearly the importance of the chemist in the modern State, though he found it necessary to urge upon his fellow chemists and other scientific workers the necessity of "throwing their weight into the scale against the tendencies which are dragging science and civilization down and debasing our heritage of intellectual and spiritual values".

ON the same day, September 10, President Roosevelt addressed a plenary session of the World Power Conference at Washington. According to the Washington correspondent of *The Times*, he said: "Your scientific and engineering genius is destroying one world—the world of relative scarcity—but has it yet undertaken to create the new world of abundance, which is potentially in your command, over natural energies ? . . . Is enough attention being paid to 'human engineering' ? In making a valuation of resources the physical and mental energies of human beings must be included." He added that a higher form of accounting is required which "takes the social values, now left to mere assumption, into its calculations and measures them". This frank statement from the leader of a great modern State, coupled with the movement from within their own ranks, will embolden scientific workers in their approach to the almost unknown fields which lie before them in social research.

Joy in Scientific Discovery

DURING the past few days, a section of the lay press has been at pains to show by word and picture—apparently as a matter for comment—that scientific workers and others at the Blackpool meeting of the British Association have made use of the means of entertainment offered by that well-known resort, even as other folk do. That men of science can also feel and show emotion and pleasure in achieving success in their own special fields of work was the theme of Prof. D. F. Fraser-Harris's public lecture "Joy in Scientific Discovery" delivered at Thornton Cleveleys on September 15 in connexion with the Blackpool meeting. While it is true that scientific men must make an impersonal study of the laws of Nature, there is ample evidence from historical records of the joy they have felt on achieving their goal. Newton, it is said, was so agitated when his work on the law of gravitation approached completion that he had to beg a friend to complete his calculation. Faraday is well known to have greeted the successful conclusion of an experiment with boyish glee, and referred in writing of the life of the man of science to "the delight which the contented mind has in acquiring it [knowledge] for its own sake". Harvey said that "the pains of discovery are amply compensated by the pleasures of discovery". Malpighi was greatly stirred by his observation of the blood streaming through the capillaries. Jenner wrote joyfully to his friend Mr. Gardner of his first successful vaccination. Pasteur had a sleepless night of anxiety when he had completed his first inoculations for rabies on a human being. Lister, a member of the Society of Friends, could write, "I don't think any case ever excited me so much", in referring to his first use of antiseptic ligatures. Graham Bell and Edison were delighted with the telephone and the phonograph respectively. Lord Kelvin, having devised a delicate electrical instrument, would have it brought to his drawing-room mantelpiece, so that he might exult over it at leisure. So the story continues. The joy of the creative intellect, whether in art, literature or science, is one of the most exalted human emotions.

Drops and Splashes

Two public lectures under the auspices of the British Association were given at Preston (September 16) and at Rochdale (September 17) by Prof. Allan Ferguson, who took as his subject "Splashes and What They Teach". The lectures dealt with the phenomena attendant on the formation and separation of a drop of water at the end of a vertical tube, the splash of a drop of liquid falling into a liquid, of a solid sphere falling into a liquid and of a drop of mercury falling on to a horizontal sheet of glass. As is well known, experiments were carried out by Worthington some forty years ago in order to elucidate some of these happenings. Photographic technique was then very primitive, and Worthington's experiments were carried out under difficult conditions. Recently a high-speed camera has been developed, in which the film is drawn continuously through the camera at a speed of about thirty miles an hour. A prism rotating rapidly about a horizontal axis is placed between the lens system of the camera and the film, and throws a picture of the object downwards on the film, so that, for a fraction of a second, the image is stationary relative to the film. In this way it becomes possible to take pictures at the rate of 2,000 a second, and therefore, by running them through a projector at the rate of 20 a second, to alter the time-scale in the ratio of a hundred to one. The films so taken corroborate in a remarkable manner the results obtained by Worthington's method of taking separate photographs of drops, each at a different stage of its fall.

Caucasian Studies

To remedy the neglect of a field in which the Russian literature, with a virtual monopoly created by circumstance, can do less than justice, a society has been founded in England for the promotion of Georgian and Caucasian studies. The promoters include Sir Oliver Wardrop and Mr. W. E. D. Allen, who are among the foremost authorities on Georgia in the West. Sir Denison Ross is the Society's first president. The Society will publish a journal under the title *Georgica*, of which the first part has already appeared. Its contents, for most of which natives of Georgia, recognized as authorities, are responsible, indicate that breadth of interest, combined with sound scholarship, will be the aim of its promoters. *Georgica* will also endeavour to keep its readers abreast of current developments in Caucasian studies not otherwise readily accessible. As preliminary matter, Sir Denison Ross contributes an introductory note explaining the objects and methods of the new society, and Mr. W. E. D. Allen reviews the present state of Caucasian studies. Among the remaining papers are a discussion of Georgian chronology by Prof. Taqaishvili, an examination of the Asianic element in Georgian paganism by Prof. M. Tsereteli (see p. 512 of this issue of NATURE), a census of Georgian manuscripts in England, of which there are three important collections, by the Archimandrite Peradze, and an account of the Holy Lance of Echmiadzin by Mr. F. J. Baddeley, who considers that it is identical with the lance discovered in the siege of Antioch in 1098. Dr. A. Gugushvili adds a valuable, if tentative, system of Georgian phonetics, which, it may be hoped, will lead to further discussion. The honorary secretary of the Georgian Society is Dr. A. Gugushvili, to whom inquiries should be addressed at Commonwood House, Chipperfield, Herts.

Exhibition of Photography

THE eighty-first Annual Exhibition of International Photography by the Royal Photographic Society was opened on September 11. It will remain open daily (Sundays excepted) from 10 a.m. until 9 p.m. (Tuesdays and Fridays excepted—lecture evenings—when it will be closed at 6 p.m.) until Saturday, October 10. Pictorial photography occupies the principal galleries and, as usual, has attracted exhibitors from all over the world. Among the scientific exhibits are two infra-red photographs taken by A. W. Stevens and O. A. Anderson from about 69,780 feet above the ground over Central South Dakota on November 11, 1935. One of these is a vertical photograph, the other lateral. The latter is said to be the first photograph to show the division between the troposphere and the stratosphere. The horizon, 330 miles away from the camera, is clearly arched. The trade sections, though not extensive, are well worth inspection. The emphasis among apparatus is upon the miniature cameras. Instructional exhibits include explanations of the working of the Pola screens and of the Kodachrome process, the effects of varying the filter in making photomicrographs of stained sections and the troubles that may arise through mishandling photographic materials.

Smoke Abatement Exhibition at the Science Museum

AN exhibition on the abatement of smoke will be opened at the Science Museum, South Kensington, by the Minister of Health, the Right Hon. Sir Kingsley Wood, M.P., on October 1, and will remain open until October 31. It has been arranged by the National Smoke Abatement Society (by permission of the director of the Museum, Colonel E. E. B. Mackintosh), with the co-operation of interested Government departments and industrial associations. Models and other exhibits demonstrating the efficient combustion of coal in steam-raising and other industrial operations will be shown, and other sections will be devoted to the uses of other natural fuels, namely, anthracite and anthracitic coals, and oil. Another section will exhibit material relating to the generation, distribution, and uses of electricity. The pre-treatment of coal will be demonstrated by exhibits on high-temperature carbonization (gasworks practice) for the preparation of town's gas and gas coke, and on low-temperature carbonization, in which the product of principal interest is the semi-coke. For the scientific investigation of the smoke problem, methods for the measurement of smoke are required, and an exhibit of the Fuel Research Station will be concerned with current researches on this subject, which are being carried out with the view of developing a domestic fire that will burn coal smokelessly. The Department of Scientific and Industrial Research will show exhibits on the nature and causes of smoke, and on the investigation of atmospheric pollution. A section of the exhibition will be devoted to material demonstrating the effects of smoke. The Annual Conference of the National Smoke Abatement Society will be held at the Museum on October 14–17, and will be opened by Captain Harry Crookshank, M.P., Secretary for Mines. Particulars of this Conference may be obtained from the Secretary of the Society, at 36 King Street, Manchester 2.

The World Power Conference

THE third World Power Conference, which was opened at Washington on September 7, was one of the largest technical conferences ever held. The British party, which travelled by the *Queen Mary*, numbered about a hundred. According to the *Electrical Times* of September 10, the records of the papers and discussions will run to more than three million words. As there was no hall in Washington large enough for a banquet of 3,000 delegates, the official banquets were held in the waiting hall of the railway station, suitably transformed for the purpose. Each country submitted papers to the Conference setting forth its own particular power problems and questions connected with them. Economic, technical and allied subjects were all discussed. The papers from each country having to be read before a mixed international audience, largely American, were naturally mainly reports of the country from which they originated. The British papers therefore were mainly of interest to all dwelling outside Britain. An exception may perhaps be made for the paper read by S. E. Britton, the city electrical engineer of Chester. His paper was entitled "Rural Electrification in Great Britain". When the use of electricity produces a revenue equal to twenty per cent of the outlay on the electrical distribution system, the inhabitants in rural areas can get a supply of electricity for all purposes at economic rates and use it for the same purposes as those residing in urban areas. Information is given of the annual expenditure on heat, light and power by those living in rural areas who use electricity and those who do not. The paper is clearly written and is very complete. It is particularly applicable to the conditions prevailing in the neighbourhood of Chester.

German Chemical Engineering

ALTHOUGH a certain amount of publicity was obtained in the scientific journals, trade papers and the daily Press for the German Chemical Engineering Exhibition held at Cologne in 1934, the organizers felt that these reports were necessarily incomplete, and so they have published the Achema Jahrbuch, 1935–36 (Berlin: Verlag Chemie, G.m.b.H.), to give some indication of the recent progress in chemical engineering illustrated by that exhibition, which was visited by 48,600 representatives of industrial firms and professional men from forty-six countries. Opportunity is also taken of directing attention to Achema VIII, which will be held on July 2–11, 1937, at Frankfort-on-Main, where accommodation amounting to 240,000 square feet of floor space will be available for exhibitors. In this exhibition, one building will be reserved for firms wishing to show scientific instruments and equipment such as are used industrially for making technical measurements or controlling and regulating the flow of fluids, heat and electricity. Another building will house industrial apparatus made of non-metallic materials, whilst the third and fourth buildings are reserved for machines used in the artificial silk and associated industries, and large-size equipment for the chemical and allied industries respectively. It is intended to publish at the beginning of 1937 a catalogue giving detailed information of the exhibition. The "Jahrbuch" also gives a list of the exhibitors at the 1934 exhibition in English, French and German as well as notes in two of these languages on some of the more important sections and the equipment which was shown.

Magnetic Observations in New Zealand and elsewhere

OWING to the world economic crisis and other causes, many magnetic and meteorological observatories, including those of some great nations, have fallen seriously into arrears with their publications. The ideal, approached, if not always attained, by the chief British observatories, is to publish the observations of one calendar year before the end of the next. Now that the great and successful co-operative effort of the Second International Polar Year has been accomplished—so far as the observations go, though the publication and, still more, the discussion of the results is still very incomplete—a desirable goal for new effort on the part of geophysical observatories would be to overtake their arrears of publication within an assigned time, say by the end of 1940. A step in this direction has been taken by New Zealand in publishing three years records of the Christchurch Magnetic Observatory in one volume (Annual Reports for 1931, 1932, 1933. Wellington: Government Printing Office, 1936. Pp. 132. 10*s.* 6*d.*). The volume naturally consists almost entirely of tabular matter, and for economy is reproduced directly from typescript, in a reasonably satisfactory manner. The magnetic data refer (as for 1930) to the Amberley sub-station, about twenty-five miles from Christchurch. Monthly mean daily variations are given for all days (with Fourier analysis) and international quiet days, but (regrettably) not for international disturbed days. The volume includes a brief seismological report for 1931. An account of the instrumental equipment of the Observatory in the introduction would have added to the convenience of users. Though the director's introduction is written in the first person, his name (Mr. H. F. Skey), by a curious oversight, seems to occur nowhere in the volume.

The Rockefeller Foundation

ACCORDING to the annual report for 1935, the Rockefeller Foundation expended 12,725,439 dollars. Of this sum 692,524 dollars was for medical education, including 460,850 dollars to the China Medical Board, 2,217,425 dollars on research programmes at universities and similar institutions, and 669,214 dollars on research programmes at research institutions and organizations. The report gives a brief description of the work of the International Health Division, the budget of which is 2,200,000 dollars; this Division covered yellow fever studies in Brazil, research on yellow fever, malaria and other diseases at the Institute's laboratories, field research on malaria in various countries, surveys to determine the status of hookworm disease in North Carolina, studies on tuberculosis, yaws and mental hygiene, as well as research on typhoid fever, smallpox vaccine and the common cold. Work in China has placed emphasis on organized efforts at rural reconstruction by assisting concrete studies and training personnel, particularly graduates, to participate in such reconstruction work.

IN the field of natural science, the Rockefeller Foundation has devoted its appropriations chiefly to research involving the application of the technique of the exact sciences to biological problems, particularly studies which contribute directly to, or form the necessary basis for, an understanding of behaviour. Grants have also been made for research on plant genetics, vitamins and hormones, physiology of reproduction and respiration, nerve physiology, etc. With regard to the social sciences, the Foundation is using its resources to develop specific areas of activity which promise to assist the solution of pressing social problems. The three areas of study thus far undertaken are social security, international relations and public administration, and the 3,807,500 dollars expended on social sciences in 1935 includes grants for research on problems of the business cycle, study of the relief situation in New York State, the Institute of Pacific Relations, agricultural economics, research on international relations and training projects in public administration.

Science in Poznań

AMONG the contributions to vol. 21 (1936) of *Nauka Polska* is a long account (pp. 70) by Prof. Z. Lizowski of the present position of science at Poznań. This ancient centre of culture in western Poland has become the most intensely Polish of all the university cities in the country, partly because 95 per cent of its inhabitants are Poles and partly because of the impetus given to its development since the liberation of the country in 1918. From the time of the partition of the ancient kingdom of Poland until the end of the Great War, Poznań was nominally a German city, and although the pursuit of scientific investigations was possible it was hampered by cultural restrictions, including the suppression of the Polish language. Since 1919, a definite revival has occurred in all branches of pure and applied natural science and the university has attracted students, lecturers and distinguished visitors from other countries.

THE international character of science has also been promoted by the lectures delivered by Poznań professors in Germany, France, the United States, Czechoslovakia and elsewhere. This issue of *Nauka Polska* also contains particulars of prizes and awards distributed to men of science and to various scientific institutions throughout Poland during the past academic year. No complete figures are given, but it seems that many thousands of pounds have been distributed. Aerodynamics, investigations on the oxides of nitrogen, Grignard's reactions, rubber research and plant physiology are among the many investigations that are being encouraged with financial assistance. In the 'foreign notes' the attention of Polish readers is directed to the Oxford conference on 'academic freedom', whilst several works by British authors are included among the books reviewed.

Rabbits in Britain

ATTENTION has been directed once again, by articles and correspondence in contemporary journals, to the damage caused by the superabundance of wild rabbits in Britain. An introduced animal, the rabbit, encouraged by conditions of soil, climate and food, has bred and spread, so that for the past century its activities have become increasingly harmful to agriculture and forestry. So long as two opposed views regarding its presence are strongly held, one emphasizing its destructiveness and the other its value as food and as an object of sport, it is unlikely that common action against the rabbit will be taken without legal compulsion. But the necessity for control in other countries and the methods employed for control are of general interest, and knowledge of them may become of great importance in Britain also, so that useful service is performed by Guy Dollman's article on "The Rabbit Menace" in the *Natural History Magazine* (5, No. 39, July 1936, p. 297), where a summary of recently developed means of limiting or eradicating the pest is given.

Research in Plant Breeding

SUPPLEMENT 2 of *Plant Breeding Abstracts*, which has been issued by the Imperial Bureau of Plant Genetics, Cambridge (price 5s.), gives a concise account of work carried on during 1932–35 on crop plants in the British Empire. It shows the great variety of plants grown and the large amount of work in progress on such crops as wheat, cotton, rice, sorghum, coco-nut, apples, etc., gleaned from more than four hundred reports in various parts of the Empire. It is so arranged that one can see at a glance, for example, the investigations of coffee that are being made in Mysore, Ceylon, Uganda, Kenya and Tanganyika, or of strawberries in England, Scotland, Canada, New Zealand and New South Wales. Work on cytology and on the genetics of plant parasites is included, and the whole serves as a very useful summary for plant breeders and geneticists. This outline picture also shows that a surprising variety of economic plants is undergoing genetic improvement.

National Research Council of Japan

The report of the National Research Council of Japan covering the period April 1934–March 1935 contains a useful list of papers published in various Japanese scientific journals during the period, together with brief particulars of divisional and committee meetings held during the year. A committee on dyestuffs research has been concerned with the investigation of standards of intermediates and dyestuffs and of the present state of industrial research on dyestuffs and chemical compounds in Japan. A further committee is concerned with radio research, and a committee on industrial research has considered the design of long-range aeroplanes, light-signalling through foggy atmospheres in daytime, the electrolytic oxidation of aluminium and its applications, material-testing by X-ray radiography and chloronaphthalenes as electrical insulators.

Conference on Bee Diseases

A conference to discuss the causes of bee diseases and the practical means of controlling them will be held on Saturday, September 26 at Rothamsted Experimental Station, Harpenden, Herts. Contributions will be presented by Dr. H. L. A. Tarr, of Rothamsted, on "Brood Diseases in England: the Results of a Three Year Investigation"; Dr. Guy D. Morison, advisory entomologist, Marischal College, Aberdeen, on "Bee Paralysis"; Dr. Otto Morgenthaler of the Bee Disease Division, Eidgenossiche milchwirtschaftliche und bakteriologische Anstalt, Liebefeld-Berne, Switzerland, on "Brood and Adult Bee Diseases in Switzerland". A paper on brood diseases in the United States specially prepared for this conference by Dr. J. I. Hambleton, Chief of the Apiculture Division, United States Department of Agriculture, will also be read.

Announcements

Sir Arthur Smith Woodward, Sir Charles Sherrington, M. Ruzicka and M. Bottazzi have been elected to the grade of associate of the Royal Academy of Belgium. Prof. F. Van den Branden, professor of clinical urology in the University of Brussels, and Prof. H. Fredericq, professor of zoology in the University of Liège, have been elected *correspondants* of the Academy.

The following appointments have recently been made in the Colonial Service: E. J. H. Berwick, to be agricultural officer, Malaya; C. E. Johnson, to be agricultural officer, Northern Rhodesia; D. R. N. Brown, J. W. Purseglove, and J. M. Watson, to be agricultural officers, Uganda; J. E. Garfitt, to be assistant conservator of forests, Malaya; N. S. Alexander, to be professor of physics, Raffles College, Singapore; J. R. Clackson, to be European assistant, East African Meteorological Service; O. T. Faulkner, director of agriculture, Nigeria, to be director of agriculture, Malaya; J. E. A. Carver, assistant conservator of forests, Nyasaland, to be conservator of forests, Mauritius; J. S. Dunn, inspector of schools, to be engineering chemist, Public Works Department, Gold Coast; H. Harrison, field assistant, to be field officer, Tsetse Research Department, Tanganyika; J. Y. Moggridge, field officer, to be entomologist, Tsetse Research Department, Tanganyika; V. Rasaretnam, assistant superintendent of surveys, to be superintendent of surveys, Ceylon; C. L. Southall, assistant analyst, Straits Settlements, to be Government analyst, Nigeria.

Prof. Carl Neuberg of Berlin, director of the Kaiser Wilhelm Institute of Biochemistry, has been elected a foreign member of the Swedish Academy of Sciences.

Prof. Friedrich Körber of Dusseldorf, director of the Kaiser Wilhelm Institute for Iron Research, has been elected a corresponding member of the Royal Swedish Academy of Engineering Science.

Applications are invited for the following appointments, on or before the dates mentioned:

A city engineer and surveyor at Lincoln—The Town Clerk, Town Clerk's Office, Corporation Offices, Lincoln (September 19).

Assistants (Grade III) in the Meteorological Office—The Secretary (S.2.E.), Air Ministry, Adastral House, Kingsway, W.C.2 (September 23).

A civilian engineer by the War Department at Christchurch, Hants.—The Under-Secretary of State (C.5), War Office, London, S.W.1 (September 25) (Quote E.B.E.).

Assistants (Grade III) in the Royal Aircraft Establishment, South Farnborough, Hants (aeronautical engineering)—The Chief Superintendent (September 26).

A temporary engineer for work at Ellesmere, Salop, on purification of milk factory effluents—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (September 30).

An assistant (Grade III) in the Air Ministry Scientific Research Pool (physics or engineering)—The Chief Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (October 2).

An organizer of technical education in the Melton Mowbray district (who in due course will become the principal of the New Technical College)—The Director of Education, County Education Office, Grey Friars, Leicester (October 7).

Assistant quantity surveyors in the Air Ministry—The Secretary (W.B.9), Adastral House, Air Ministry, Kingsway, W.C.2.

Letters to the Editor

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 511.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Chemical Composition of the Planetary Nebulæ

THE physical conditions in the planetary nebulæ are such that atoms or ions in metastable states are not disturbed by electron impact or the absorption of radiation during their lifetimes of one minute or more. The intensity of a 'forbidden' emission line (due to transitions from such a metastable state) is then[1] $I=nh\nu$, where n is the number of ions arriving in the metastable state per second, and $h\nu$ is the energy emitted from each transition. It is possible to determine the relative abundance of ions in the nebulæ from the observed[2] intensities of their forbidden lines (listed in cols. 5 and 7 of the Table), if, following Bowen, we assume the excitation to the metastable state to be due solely to inelastic electron collisions, that is, n is proportional to $N(w)p(v,w)\rho(E)$, where $N(w)$ is the number of ions of atomic weight w per c.c., $p(v,w)$ is the probability of electron collision and resultant excitation, and $\rho(E)$ is the number of electrons per c.c. with kinetic energy greater than the excitation potential, E, of the ion.

The 'nebular' lines (that is, lines due to the shortest forbidden transition to the ground state) of five ions are listed in column 3 of the table (the 'transauroral' lines of S+ are included). They are in the range λ6600–λ3800 and therefore have excitation potentials, E (col. 4), between 1·9 and 3·2 electron volts, corresponding to a range of 25 per cent in v, the electron velocity. If we assume that $p(v,w)$ is constant in the small ranges of v and w here involved, the relative numbers of quanta in the forbidden lines, $I/h\nu$, derived from the intensities in cols. 5 and 7, are proportional to the numbers of ions in the nebula. With O++ as standard, these values are lower limits to the relative numbers of ions when the excitation potential is greater than the 2·5 volts of O++, because there are fewer electrons available to excite such ions (that is, $\rho(E)$ is smaller than for O++); otherwise they are upper limits as indicated in cols. 6 and 8.

With a knowledge of the temperature of the ionizing radiation and its dilution, we can use the ionization formula[3] to determine the relative abundances of the elements from the proportions of their ions. The central star temperature is 50,000° K. for the nebula N.G.C. 7027 and the dilution (which is not simply geometrical dilution, but complicated by absorption in the inner layers of the nebula) was calculated from the measured ratio $O+/O++=5\times10^{-3}$. (This was derived by the above method from the intensities of λ5007 and λ4959 relative to λ3726 and λ3729, the nebular lines of O+, given by L. Berman[4]. Berman's published ratio must be corrected by +1·09 mag.) In this manner we arrive at the abundances listed in col. 9, corrected to relative numbers of atoms of the elements (for N.G.C. 7027). The proportions of oxygen, neon, and argon are approximately the same as of their ions, O++, Ne++, and A+++, because their ionization potentials (given in col. 2) are so nearly equal. The N+ and S+ ions, however, form only a small fraction of the total amount of nitrogen and sulphur, which are present mainly as N+++ and S++++, and therefore the determination of nitrogen and sulphur content is of low accuracy.

The most surprising of these first quantitative results is the high abundance of neon and argon in the nebula. If the identification of the forbidden lines and also our assumptions are correct, we must explain a ratio of neon to oxygen 10^6 times as great and a ratio of argon to oxygen 10^3 times as great as on the earth (last col. of the table). There are two

Element At. Wt., w	Ion Ion. pot.	Forbidden lines	Classification[1] E	N.G.C. 7662		N.G.C. 7027			Earth[3], abundance of atoms
				Line Int. I	Abundance of ions, N	Line Int I	Abundance of ions, N	Abundance of atoms	
N 14	N^+ 14·48v.	λ6583 6548	$^3P-^1D$ 1·9v.	... .	..	26[4] ...	<0·21	$<6\ 5\times10^{-2}$	$9{\cdot}3\times10^{-4}$
O 16	O^{++} 34·98v.	λ5007 4959	$^3P-^1D$ 2·5v.	84[2] 32[2]	1·00	118[4] 42[4]	1 00	1·00	1·00
A 40	A^{+++} 40 78v.	λ4740 4711	$^4S-^2D$ 2·6v.	.. 0·98	$>7\times10^{-3}$	0·70	$>5\times10^{-3}$	$>8\times10^{-3}$	$3\ 2\times10^{-6}$

possibilities: either (1) the nebulæ are normal in composition and the earth has lost neon, nitrogen, and argon, or (2) the earth is normal, and the nebulæ are low in oxygen and argon content relative to neon.

As regards (1), Russell and Menzel[5] have shown that light gases such as neon and nitrogen would completely disappear from the earth, if and when it were hot enough, long before heavier gases like argon even began to escape. Possibility (2) might be caused by the oxygen and argon at the low black body temperature in the nebula (15° to 20° K.) freezing out on dust particles (the presence of which in the nebulæ has already been suggested on other grounds[4]). The freezing points are: oxygen, 55° K.; argon, 85° K.; nitrogen, 62° K.; neon, 20° K. Unless almost all the oxygen were in combination in the dust particles, however, this still leaves unexplained the high content of argon which, freezing at a higher temperature than oxygen, should be more completely solidified.

We conclude that there is as yet no completely satisfactory explanation of these abundances.

Radioactive Isotopes of Bromine

FERMI and his collaborators[1] detected two unstable isotopes of bromine characterized by half-periods of eighteen minutes and 4·2 hours. The nuclear transformations are probably expressed by the equations:

$$(1)\quad {}^{79}_{35}\text{Br} + {}^{1}_{0}n \rightarrow {}^{80}_{35}\text{Br} \rightarrow {}^{80}_{36}\text{Kr} + e^{-};$$

$$(2)\quad {}^{81}_{35}\text{Br} + {}^{1}_{0}n \rightarrow {}^{82}_{35}\text{Br} \rightarrow {}^{82}_{36}\text{Kr} + e^{-}.$$

The isotopes 80, 82, of krypton are normal constituents of the element.

We noticed that when pure liquid bromine was exposed to neutrons for a week and then transferred to a thin-walled cylindrical glass cell encompassing a Geiger-Müller counter, the instrument registered twenty impulses per minute after a lapse of thirty hours. Previously we had observed the phenomenon in silver bromide precipitated from an irradiated aqueous solution of ammonium bromide. The time of half-decay is provisionally estimated to be twenty-four hours.

As a result of many experiments we conclude that the following reactions occur very infrequently, if at all:

$$(3)\quad {}^{79,81}_{35}\text{Br} + {}^{1}_{0}n \rightarrow {}^{79,81}_{34}\text{Se} + {}^{1}_{1}\text{H};$$

$$(4)\quad {}^{79,81}_{35}\text{Br} + {}^{1}_{0}n \rightarrow {}^{76,78}_{33}\text{As} + {}^{4}_{2}\text{He}.$$

Selenium, and arsenious sulphide, precipitated from irradiated solutions of ammonium bromide exhibit no long-period activity. This excludes, in particular, ${}^{76}_{33}\text{As}$ ($t_{1/2} = 26$ hours) as a possible source of the 'twenty-four hours' activity. The likelihood that it is due to another radioactive isotope of bromine or to an excited bromine nucleus is strengthened by the fact that we have not succeeded in separating the 'twenty-four hour' period from the other two; that is, all three activities in nearly the same relative proportions (small variations would be anticipated) have been observed irrespective of the form in which bromine is presented to the counter. Up to the present, *bromine*, *ammonium bromide*, *silver bromide*, *lead bromide*, and *ethylene dibromide* have been examined. To an irradiated solution of ammonium bromide, arsenic and selenium compounds were added, and pure samples of the three salts obtained from the mixture. Ethylene dibromide was prepared from radioactive bromine.

When, as in this case, the number of recognizable half-periods exceeds the number of isotopes in the natural element, several hypotheses can be suggested to explain their origin. Moreover, the half-periods are often difficult to determine precisely, and may sometimes be compounded of two or more. If there are, in fact, only three periods characteristic of bromine, the simplest explanation appears to be that a neutron is either absorbed, equations (1) and (2), or causes the expulsion of another neutron, thus:

$$(5)\quad {}^{79}_{35}\text{Br} + {}^{1}_{0}n \rightarrow {}^{78}_{35}\text{Br} + 2\,{}^{1}_{0}n;$$

$$(6)\quad {}^{81}_{35}\text{Br} + {}^{1}_{0}n \rightarrow {}^{80}_{35}\text{Br} + 2\,{}^{1}_{0}n.$$

Fermi[1] discussed this type of collision, but did not observe it. Bromine atoms of mass 80 are produced by reactions (1) and (6), and until a fourth half-period can be shown to exist must be presumed identical. The isotope ${}^{78}_{35}\text{Br}$ may emit a *positron* or an electron, becoming ${}^{78}_{34}\text{Se}$ or ${}^{78}_{36}\text{Kr}$. These are stable.

In our experiments the substances were exposed to fast and slow neutrons (and γ-radiation) produced by a mixture of beryllium dust and radium bromide. Fast neutrons are probably required to bring about reactions (5) and (6). The effect of varying the relative concentrations of slow and fast neutrons will shortly be investigated. The main results are summarized in the accompanying table:

Half-period	Relative initial activity	Relative total activity
18 min.	8	1
4·2 hours	3·5	6
24 hours (?)	1	10

Figures in the third column are proportional to the total number of impulses given to the Geiger-Müller counter during the whole period of decay. They are of interest in connexion with the hypothesis suggested above, wherein isotope 82 is produced by absorption of a neutron, 78 by disintegration, and 80 by both processes, but an attempt to assign half-periods to particular isotopes would be premature at this stage.

Neutron Absorption of Boron and Cadmium at Low Temperatures

IN the same arrangement as used for silver absorption[1], we have measured the influence of temperature on the absorption of neutrons in Fermi's group 'C' by boron and cadmium, using the 2·3 min. silver activity as detector.

Absorption curves were taken with detector, source and absorber kept at room temperature in the centre of a large vessel containing liquid hydrogen (20·4° K.) or water (300° K.). The ratio of thickness giving equal absorption at different temperatures, $\sqrt{(300)}/\sqrt{(20{\cdot}4)}$, was found to be fairly independent of the absorption itself, its value being $1{\cdot}65 \pm 0{\cdot}20$ for boron and $1{\cdot}4 \pm 0{\cdot}25$ for cadmium.

The theoretical value to be expected from a $1/v$ law of absorption, assuming a Maxwell distribution, would be 3·84. Preliminary results on cadmium absorption in paraffin cooled by liquid nitrogen (77° K.) gave, for $\sqrt{(300)}/\sqrt{(77)}$, a value less than 1·1 in agreement with the results of Rasetti, Segrè, Fink, Dunning and Pegram[2] with the mechanical selector, and those of Dunning and others[3], obtained at 85° K. We therefore conclude that the absorption curve of cadmium has a selective character, though comparison with 20·4° K. shows that an increase of cross-section certainly exists at the lowest energies, presumably due to overlapping of a selective band with the usual increase obtained with most elements at very low energies.

The results with boron cannot be explained on the assumption of a $1/v$ law for both boron and silver, but it is not possible to decide whether this is not due to the deviation of the silver detector alone from the $1/v$ law, since experiments have not yet been made with a boron chamber as detector.

The State of Ascorbic Acid in Plant Tissues

DURING the last two years, considerable discussion has arisen over the state in which ascorbic acid occurs in natural food materials. It is an experimental fact that some vegetables after being heated in boiling water exhibit an apparent increase in the amount of titratable ascorbic acid, which can then be extracted from the plant tissues.

Three explanations for this anomalous increase have been advanced:

(1) Heating breaks up the cellular tissue and allows a more complete extraction of ascorbic acid[1].

(2) A part of the ascorbic acid exists in a combined or esterified form which is hydrolyzed by heat or acid[2,3].

(3) Heating inactivates the oxidizing enzymes, thus preventing the oxidation of ascorbic acid[4].

The first explanation has been discarded, but the (2) and (3) have provided the basis for the present controversy. As a matter of fact, all the phenomena were noted by Tillmans and his associates[5] several years ago. They state that with certain vegetables the proposed titrametric method agreed with the biological assay method only if the oxidized ascorbic acid were reduced with hydrogen sulphide. The oxidation of ascorbic acid occurred during the extraction and might be prevented by heating before extraction or by extracting with stronger acid.

These facts have been insufficiently realized by later workers. Thus, Ahmad[2] considers that no oxidase was concerned, since raw cabbage extracted with cold 20 per cent trichloracetic acid gave a lower titre than boiled cabbage extracted with the same acid. The assumption that 20 per cent trichloracetic acid completely inhibits the enzyme action in cabbage is erroneous. In a forthcoming communication from this laboratory, it is shown that while the optimum *p*H for the reaction of ascorbic acid oxidase is about 5·5, a considerable activity persists at very much lower *p*H values. Although an oxidizing enzyme has been found in every one of nine vegetables investigated, its activity varies greatly. The oxidase in cabbage is barely inhibited by extraction with 1 *N* sulphuric acid, in which case the *p*H of the extract is 0·8. Furthermore, it should be realized that while the final concentration of an extract may be 20 per cent trichloracetic acid, it is very much less than that in the crushed plant cells during the first few moments of grinding up the vegetable.

Recently, Guha and Pal[6] have reported experiments which are claimed to demonstrate almost conclusively that the increase in ascorbic acid content of certain foodstuffs on boiling cannot be accounted for on the oxidase theory. Alcoholic and ethereal extracts of cabbage are claimed to give an increase in ascorbic acid after heating. It should be pointed out that ascorbic acid oxidase is completely inactivated by both absolute alcohol and ether. Therefore any increase in ascorbic acid on heating these extracts has no bearing whatever on the oxidase theory, but must be explained by other means.

EXPERIMENTAL PROCEDURE

Treatment	Ascorbic acid (mgm. per gm. of vegetable) Before Reduction with H_2S	After Reduction with H_2S
1. 20 gm. cabbage extracted with 100 ml. cold water	0·003	0·50
2. 20 gm. cabbage covered with 40 ml. cold water and heated 4 min. at 100° C. under CO_2. Extracted with 60 ml. additional water	0·47	0·48
3. 20 gm cabbage extracted with 100 ml. cold 1*N* H_2SO_4 containing 2 per cent HPO_3	0·50	0·51
4. 20 gm. cabbage + excess Na_2SO_4 extracted with 100 ml. cold anhydrous ethanol	0·51	0·54
5 20 gm. cabbage + excess Na_2SO_4 extracted with 100 ml cold anhydrous ethyl ether	0·004	0·03
6. Extract (1) heated 4 min. at 100° C. under CO_2	0·04	0·47
7. Extract (1) made 0·2 per cent with resp. to HCl, let stand 1 hour	0·006	0·43
8. Extract (1) made 1 per cent with resp. to HCl, let stand 1 hour	0·008	—
9. Extract (4) heated 4 min. at 100° C. under CO_2	0·50	—
10. Extract (4) heated 10 min. at 36° C. under CO_2	0·47	—
11. Extract (5) air dried, then heated in 50 ml. water 4 min. at 100° C. under CO_2	0·004	—

I have carefully repeated the experiments of Guha and Pal and failed to observe any increase in ascorbic acid content on heating. Instead, the results show that the samples of cabbage examined in this laboratory did not contain appreciable amounts of ascorbic acid in a combined state. If the enzyme is inactivated by heat or alcohol, or inhibited by extracting with *sufficiently strong acid*, the total amount of ascorbic acid is obtained. The fact that practically none of the ascorbic acid is recovered by acidifying or heating an aqueous extract indicates that nearly all the apparent increase on cooking is due to the inactivation of the enzyme. The slight increase on heating the aqueous extract may or may not be due to the liberation of bound ascorbic acid. I do not regard it as evidence of the existence of an ascorbic acid ester in natural foodstuffs.

Phosphagen in Echinoid Muscle and in Electrical Tissue

IT has been shown[1,2] that the electrical organs of *Torpedo* contain phosphagen, thus adding another to the series of resemblances already known to exist between electrical and muscular tissue. The possibility that both tissues may make use of the same or similar chemical mechanisms led us to study the electrical cells of *Torpedo* from the point of view of the interrelationships of certain of the phosphorylated compounds believed to be concerned in muscle chemistry.

It was found that the partition of phosphorus in the tissue is very like that in the muscles of the rat and the frog, and the following observations all serve to confirm the close resemblance already mentioned. (1) Extracts and breis prepared from the electrical organ will synthesize creatine phosphoric acid from creatine and phosphoglyceric or phosphopyruvic acid in the presence of adenylpyrophosphate or adenylic acid under conditions which lead to a similar synthesis in muscle preparations. (2) In dialyzed extracts this synthesis is catalyzed by the magnesium ion. (3) Phosphoglyceric acid is converted into pyruvic acid (demonstrated by the nitroprusside reaction and by the formation of a crystalline 2–4–dinitrophenylhydrazone). (4) Phosphagen can be synthesized from adenylpyrophosphate in high concentration without the addition of phosphoglyceric or phosphopyruvic acid. (5) Adenylpyrophosphate is rapidly dephosphorylated by such tissue preparations.

Hence this electrical tissue, like muscle, contains enzymes capable of catalyzing the following reactions :

(1) Phosphoglyceric acid → phosphopyruvic acid ;
(2) Phosphopyruvic acid + adenylic acid → adenyl pyrophosphate + pyruvic acid ;
(3) Adenylpyrophosphate + creatine → adenylic acid + phosphagen ;
(4) Adenylpyrophosphate → adenylic acid + phosphoric acid.

It therefore seems very probable indeed that the cells of muscle and of the electrical organ of *Torpedo* alike derive the energy for their activity from the same chemical sources through the same chemical mechanisms, a suggestion which harmonizes with the well-known parallel between the physiological and pharmacological behaviour of the tissues in question, and the fact that they are both derived from embryonic pre-muscular rudiments.

Needham, Needham, Baldwin and Yudkin[3] reported the presence in the jaw muscles of *Paracentrotus* of two phosphagens, believed to be the phosphoric acid compounds of creatine and arginine respectively. In view of the phylogenetic interest[4] of these results we have studied the behaviour of certain phosphorylated compounds in the presence of enzyme extracts, prepared from the jaw muscles of *Sphærechinus granularis*, and have been able to demonstrate the synthesis of two phosphagen-like compounds from creatine and arginine respectively. The first of these behaves exactly in the way expected of creatine phosphoric acid, and in view of the results already reported by Needham, Needham, Baldwin and Yudkin, is almost certainly that compound. The second, synthesized by the enzyme preparations from arginine, behaves, so far as we can determine, like arginine phosphoric acid. Its hydrolysis is considerably retarded by molybdate, and the base liberated by the hydrolysis gives the Sakaguchi reaction and, when submitted to the action of arginase prepared from rabbit liver, gives quantitative yields of urea.

All the evidence we have obtained confirms the existence in echinoid jaw muscle of enzymes analogous to, if not identical with, those found in the muscles of other organisms and, as reported above, in the electrical organ of *Torpedo*, and we have found no reason to suppose that the mechanisms involved in the synthesis of the two phosphagens differ essentially from those demonstrated in vertebrate muscle by the Parnas school[5] and Needham and van Heyningen[6], and in arthropod muscle by Lehmann[7].

This confirmation of our earlier results makes us feel justified in laying considerably more emphasis than hitherto upon the phylogenetic significance of these purely biochemical results.

Swarming of the Males of Certain European Anophelines in Captivity

THE study of the biology of the European *Anopheles*, particularly the complex of forms known as *Anopheles maculipennis*, has been greatly hampered by the difficulty of inducing mating under laboratory conditions. Missiroli and I[1] have given a summary of the experiments made with these mosquitoes, of which only the 'race' known as *atroparvus* has mated in captivity. In this form, it appears that there is no sexual dance on the part of the males as a preliminary to mating. Curiously enough, females of all the races will mate with *atroparvus* males, but repeated attempts on the part of many investigators to get them to pair with males of their own kind have failed.

Some years ago, I constructed a large cage of wire netting, 10·5 metres long, 5 metres wide, and 6·2 metres high, in connexion with the malaria laboratory in Albania. The cage was designed for the observation of the behaviour of *maculipennis*, and an attempt was made to make the conditions within the enclosed area as natural as possible. A cement pool, a stable, a small laboratory, and a tree were included within the cage. Fertile *typicus* eggs were found in the pool in 1934, but in small numbers compared with the quantity of mosquitoes released, and no sexual activity was observed in the cage. Between June 19 and July 12, 1936, we released in the cage 4,500 adults of *typicus* bred from the egg, and on July 7 we first observed swarming of the males, although larvæ had been found in the pool some days previously. Since then we have found the males swarming almost every evening, the swarm usually starting between 7.15 and 7.30 p.m., and the principal swarm always forming in the same position: about half a metre beneath the top of the cage, directly under one of the cross beams, and about half a metre from one of the upright poles supporting the side. This orientation, under the cross beam, seems very curious, and we should consider it to be fortuitous were it not repeated so frequently.

The wire cage is, of course, completely open to external stimuli, and we have been carrying on some experiments in the opposite direction: in a room insulated so far as possible from external stimuli, so that all the reactions of the mosquitoes would be to factors within the room. The room used is 2·5 metres long, 2·3 metres wide and 2·6 metres high. It is constructed of mud brick, with an air space between the ceiling and the roof; the windows are kept closed and have been covered on the outside with canvas curtains, so that the maximum light during the day is only about five foot-candles. The climate within the room remains remarkably constant, the temperature showing a diurnal fluctuation of about 5° around a mean of 20°, the humidity varying between 84 and 94 per cent. We released in this room about a thousand *maculipennis* adults bred from *typicus* eggs, but we did not observe any sexual activity, and we only obtained two batches of fertile F_1 eggs. At the same time, about 600 *Anopheles superpictus* were released in the room, and the males of this species were found to swarm under these conditions very readily, and numerous fertile *superpictus* eggs were found in the aquarium in the room. Up to July 27 we had released in the same room about 500 *Anopheles elutus*, raised in the laboratory. The males were first observed swarming on July 28, and afterwards batches of fertile eggs were found in the aquarium.

We are thus able to observe under varying conditions the sexual activities of the three malaria vectors of Europe. A few *bifurcatus* were also released in this room, and one evening four or five males were observed forming a swarm, and fertile eggs of this species were afterwards obtained.

Persistence of the Eel-Grass Disease and Parasite on the American Atlantic Coast

EARLY in the summer, through facilities extended by Mr. John Lynch, of the U.S. Biological Survey, I was able to make a number of investigations of the existing eel-grass beds along the middle Atlantic coast, in the range of Cape Cod, Massachusetts, to Barnegat Bay, New Jersey. Mr. Lynch also supplied me with systematically taken specimens from beds farther north and south, Casco Bay, Maine, to Chesapeake Bay, Maryland, and with repeated observations from a number of points between. These studies were undertaken to discover to what extent the increasing number of optimistic reports concerning new and larger beds might indicate an effective return of the plant. For the greater part such reports describe late spring growths, during the season of rapid vegetative development, and give no clue of the plant's ability to withstand conditions arising in the less favourable warmer months, when the parasitic *Labyrinthula* is most active, or of its value as winter food for migratory birds, a matter of practical concern.

At the time of the first survey, in early June, small scattered beds of eel-grass, varying in vigour, were found all along the coast so far south as the northern end of Barnegat Bay, and extensive beds of small-leafed growths were described in the eastern shore of Chesapeake Bay, where the latter was being used for packing material. Barnegat Bay and the Delaware coast were notably free from the plant, as were the relatively rocky bays of the Connecticut coast.

The shallow bays of Long Island, Rhode Island, and Massachusetts bore patchy beds often several acres in area, and these were underlaid by extensive mats of healthy stem stock. These beds could conceivably be of ecological value, especially those along Rhode Island and Massachusetts, where the leaves averaged a metre in length, and foliation was relatively dense.

In all beds studied some plants were in seed, and, I understand from Mr. Lynch, a large fraction in the beds south of Cape Cod are now seeding. Seeds have been produced early in the summer for the past three years. It is surprising, therefore, to find but few seedlings even among the scattered plants in what appear to be new beds. Most shoots can be traced back to stem stock one or two seasons old, not very vigorous stock as a rule. If the beds continue to propagate mainly from stem stock, progress will be slow, even under favourable conditions of competition with the parasite.

Symptoms of the wasting disease were present everywhere in June, but there seemed to be no correlation between density of growth and infestation. The wasting is now at its height, so that some beds, as in Great Bay, Long Island, have entirely disappeared.

Specimens from all beds visited were examined microscopically for the *Labyrinthula* described in NATURE last year, and with which confirmatory inoculation experiments have since been performed[1,2]. Without exception it was present and active in streaked or mottled leaves, and in many regions it had already caused considerable wasting.

If previous experience may be taken as an indication, the following seasonal sequence may be expected: Very slow winter growth of the *Zostera* with the *Labyrinthula* passive in the leaves (the spindle form of the parasite has been found in winter specimens), rapid vegetative development in the late spring, with slight increase in activity of the *Labyrinthula*, diminution in the vitality of the plant prior to seed formation in the early summer with sudden activation of the parasite, destruction of leaves, development of new leaf shoots and their subsequent destruction (repeated several times in mid-summer), and final exhaustion of a portion of the stem stock and dying back of part of the bed developed earlier. A number of plants will seed prematurely, or will appear to because more retarded members die off before the normal fruiting period is finished. Barring the development of resistent strains of *Zostera* or general attenuation of the parasite, this seems to be the probable cycle within any progressive return of the plant. This, I realize, is not a cheerful interpretation, but it will be recognized that readjustments no less drastic, but easily overlooked, occur constantly.

I should be grateful to readers of NATURE for particular information on local conditions of the eel-grass in England and on the Continent.

A Case of Complete Reversion of a Chromosomal Rearrangement in *Drosophila melanogaster*

THE process of gene mutation is known to be reversible, since back-mutations occur both spontaneously and under X-ray treatment. Yet no authenticated case of a complete reversal of a gene rearrangement has hitherto been observed. Muller and Stone[1] induced a partial re-inversion of the *ClB*-inversion of the *X*-chromosome, but neither of the new breaks corresponded to the original *ClB* breaks. A spontaneous re-inversion of the same inversion observed by Gershenson[2] has not been completely analysed; so it remains doubtful whether in this case old and new breaks coincided precisely.

In 1935, I described[3] a very long inversion of the *X*-chromosome induced by X-rays which was inseparably associated with a 'gene' for very rough eye-surface. In a stock homozygous for this inverted chromosome and carrying several recessive markers, animals with normal eye-surface appeared. Contamination was excluded by the fact that all the other factors were still present. A thorough genetical analysis showed that in these animals not only the rough eye-surface 'gene', but also the inversion had disappeared, and that old and new breaks were identical. This has since been checked up cytologically by my colleague, Mr. C. W. Emmens, in the salivary gland chromosomes.

The rough eye-surface associated with the inversion behaves allelomorphically with the factor roughest[3]. Genetical and cytological methods have hitherto failed to reveal any signs of a chromosomal abnormality associated with that mutant. Nevertheless, it remains still possible that roughest[3] is a position effect too minute to be demonstrable with our present methods.

This seems to be the first case in which a complete reversal of a gene rearrangement has been demonstrated by all available criteria. At the same time, the case furnishes crucial evidence for the existence of a position effect, since phenotypic effect and inversion appeared and disappeared simultaneously.

A detailed analysis of the case will be published in the *Journal of Genetics*.

Different Results in Reciprocal Crosses between Diploid and Triploid *Allium Schœnoprasum* L.

IN the summer of 1934, crosses were made between diploid forms of chive ($2n=16$) and artificial triploids ($2n=24$)[1]. The somatic chromosome numbers in the progeny of these crosses have now been determined for 100 plants and are shown in the accompanying table.

The results exhibit a decided difference, according to whether the diploid or the triploid was used as the mother plant. In the former case, the majority of the progeny obtained were diploids, only 18 out of 71 plants having different chromosome numbers, namely, $2n=22$–24. In this cross the numbers 17–21 were not found at all. If, on the other hand, the triploid was used as the mother plant, all chromosome numbers between 16 and 24, except the number 20, were obtained. The trisome class, $2n=17$, which was not formed in the former case, was now the one most numerously represented. In addition, there also occurred one plant with 28 chromosomes, the result of the functioning of a giant gamete.

Direction of cross	Chromosome number of the progeny										Total of plants
	16	17	18	19	20	21	22	23	24	Med.	
$2x$ ♀ × $3x$ ♂	53	0	0	0	0	0	4	11	3	17·8	71
$3x$ ♀ × $2x$ ♂	8	9	1	2	0	4	1	2	2	18·5	29

It is obvious that the effect of the elimination or non-formation of aneuploid zygotes is greater when the embryo develops on a diploid than on a triploid plant.

These results are in agreement with earlier work on reciprocal crosses between diploids and triploids, for example, in *Oenothera*[2] and *Zea*[3].

The Feulgen Reaction of the Bacteriophage Substance

THREE years ago, a method was described which yielded pure preparations of a *Coli* bacteriophage of large particle size (*WLL*) in weighable quantities[1]. The high phosphorus content (3·7 per cent) of these preparations and their high affinity for basic dyes suggested—in connexion with other analytical results—that the chief constituent of the particles was of nucleoproteid nature[2].

It has now been found that they are intensively stained by Feulgen's reagent, generally regarded as a histo-chemical reagent for thymonucleic acid. Bacteria and bacterial debris (even a concentrated preparation of debris of phage-size obtained by lysing the organism with the very small phage *S*13 which afterwards could be removed by washing) treated in the same way remain unstained. So the phage-substance seems to be chemically different from any constituent of the bacterial cell normally present in significant amount.

The concentrated and purified preparations of a *Staphylococcus* phage obtained recently by Dr. Elford show exactly the same staining reactions as the *WLL-Coli*-phage.

Lightning and Atmospherics

IN NATURE of August 15, on p. 278, I notice a paragraph dealing with atmospherics produced by lightning discharges. From my own observations, I would express the opinion that the statements made in that paragraph only represent a part of the complete picture. There are so many different kinds of atmospherics observed both aurally in radio receivers and visually when they are recorded as by means of cathode ray oscillographs, that a complete generalization in such simple terms as are there expressed is scarcely possible.

With certain classes of atmospherics, in some cases quite a prolonged crackling can be observed lasting as much as a second before the lightning flash is observed visually. In such instances the crackling, one can only presume, arises from initial priming discharges somewhat in the nature of long brushing streamers, such as may be observed with high-tension electrical test apparatus, which brushing ultimately culminates in a complete sparkover. In all cases of observed atmospherics of this nature, the crackling sound of more or less prolonged duration finishes with a loud crack coincident with the final sparkover, which is observed as the visible lightning flash.

This type of atmospheric is only observed with certain forms of thunderstorms and is by no means of general occurrence. In many cases the sounds heard are of a simple click nature, which corresponds to straight sparkover without the preliminary brushing discharges giving the prolonged crackling sounds.

So far as my own observations go, the type of atmospheric particularly referred to, which gives the long crackling noise followed by the final crack of the sparkover, is a much rarer form than the simpler types in which it is obvious that the sound accompanies the visual flash. It is possibly for this reason that little notice has been taken of this form of discharge.

Colloid Substrate in Photosynthesis

IN an earlier note on this subject[1] it was recorded that in the interaction of two salts in an aqueous medium, leading to the formation of periodic structures (mineral arboreal growth), a colloidal condition is created in the medium, this state remaining stable under the original experimental conditions.

Since then, it has been observed that whilst periodic structures find their existence above the transition point of the colloid to the physico-chemical associations approaching double salts, the range of the colloid state is much wider, extending both above and below this transition point. Thus in the interaction of calcium chloride with sodium carbonate, arboreal growth appears above the hydrocalcite to calcite transition point, that is, at 10°–12°[2] with a range of formation of 10°–12°. But the systematic formation of the colloidal phase itself commences with the appearance of the gelatinous membrane at the interface of the two electrolytes at about 4°, and is produced regularly so long as this membrane exists.

Close observation showed that the colloid was not always confined to the aqueous medium. Very often it was also dispersed in the air above it. During the eruptions from the membrane-protuberances, effervescence on the surface of the liquid could be frequently observed, and by means of a narrow parallel beam of light from a Miller projecting lamp, the Brownian movement of finely divided colloidal matter could be seen in the space above the liquid. The evolution of this effect depended on such experimental conditions as osmotic pressure, height of column of liquid above membrane and character of membrane itself.

In the light of researches by Baly, Dhar and others on photosynthesis, these observations when applied to marine and atmospheric surroundings appear to have an important bearing upon natural phenomena. Details of this work are to be published elsewhere.

Indication of a Decrease in the Polarizability of a Non-Polar Molecule by Pressure

SOME years ago, results were published of measurements on the dielectric constant of carbon dioxide under pressures up to 1000 atm.[1]. Using Amagat's isotherm data, where available, the Clausius Mosotti function $P = \frac{\varepsilon - 1}{\varepsilon - 2} \times \frac{1}{d}$ was calculated; P is proportional to the polarizability of the molecule. It was stated that P showed a tendency to decrease, the decrease at 1000 atm. being about 1 per cent. It was considered not impossible at that time that this decrease was due to an uncertainty in the density d.

Lately more accurate isotherms of carbon dioxide have been published[2]. Using these data, the value of P has been recalculated. As an example of the results, values of P have been plotted in Fig. 1 against density, and in Fig. 2 against pressure. It can be seen that P decreases with pressure and this decrease is obviously more simply related with the change in pressure than with the change in density.

There are two possibilities to account for this effect. The first is, that the Clausius Mosotti expression is not the exact relation between the polarizability of the molecules and the dielectric constant; the second one is, that the polarizability of a molecule is really decreased by pressure. With regard to the first possibility, it must be remembered that a rigorous proof of the Clausius Mosotti expression has not yet been given, and it is possible that the assumptions necessary to arrive at the formula do not hold under the present conditions. From the way in which the formula is deduced, and from a recent discussion by Darwin[3], it can be expected that, if corrections to the simple Clausius Mosotti expression are necessary at higher densities, these will be functions of density, which will not strongly depend on temperature. This view is, however, in contradiction with the experimental data.

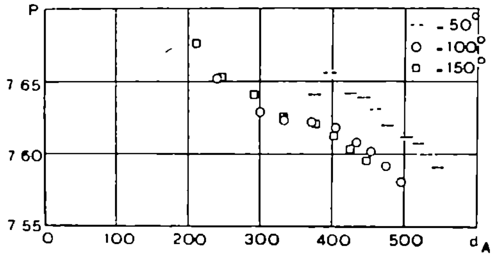

FIG. 1.

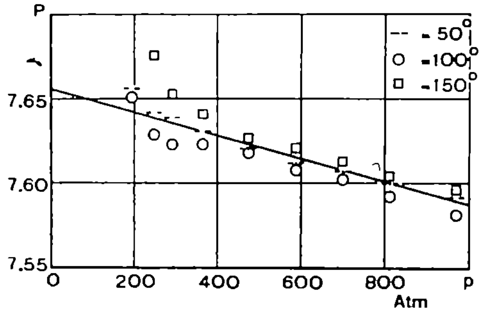

FIG. 2.

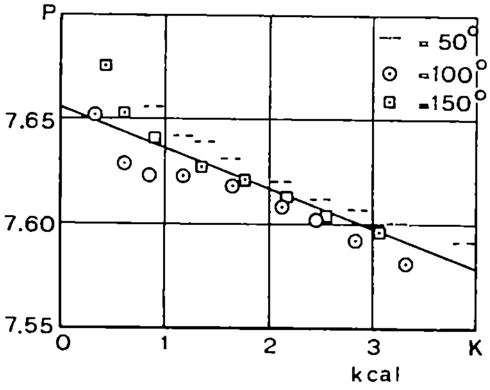

FIG. 3.

In favour of the second possibility, an argument can be given making use of the virial theorem. If the constituent parts of the molecule, that is, nuclei and electrons, are treated as separate particles, all the forces acting between those particles are Coulomb forces. The virial theorem applied to such a system leads to

$$3\Delta pv = \Delta K + \Delta U^4.$$

where pv is the product of pressure and volume, U is the total energy of the system, and K is the sum of the kinetic energies of all particles. For an isothermal compression the kinetic energy of the molecules (for example, translational and rotational) is constant by the equipartition law. Therefore ΔK measures the increase of the kinetic energy of the internal motion of the molecules (for example, kinetic energy of nuclear vibrations and electronic motion) and can be considered as a useful measure of any alteration inside the molecule, caused by compression. It is, therefore, apparent that a relation between ΔK and P must be sought.

In the case of carbon dioxide, ΔK—which can be calculated from isotherm data—amounts to 3·5 kgm. cal./mol. at 1000 atm., or 0·15 e.v. per molecule. It changes almost linearly with p, and is affected only slightly by temperature. The simple relation found between P and pressure therefore points to a similar relation between P and ΔK. In Fig. 3, P is plotted as a function of ΔK, for three sets of measurements at different temperatures, and it can be seen that, within the experimental accuracy, P is a linear function of ΔK. (The uncertainty in P is estimated as ± 0·03 at density 200 A.; ± 0·015 at 400 A.; ± 0·01 at 600 A.)

Excitation of Raman Spectra of Substances with the aid of 'Optical Catalysers'

IN a recent paper[1], we have shown that the infrared frequencies of glass can be calculated by taking the wave-lengths of the maxima of absorption bands of didymium glass as the incident exciting radiations, and those of the maxima of the fluorescent bands of the same glass excited by sunlight, as the Raman lines. The values thus obtained are in excellent agreement with those obtained for glass by the usual method of experimentation using a mercury lamp and many hours of exposure.

Following the same method of experimentation, we have now extended our observations to water, methyl alcohol, ethyl alcohol, acetone, pyridine and nitric acid solution in water. In order to produce absorption bands in these media, a trace of potassium permanganate was added to each of the above substances. The corresponding fluorescent bands obtained with sunlight were photographed. The duration of exposure varied, from two to three hours giving sufficiently strong bands on development of the plate. From the wave-lengths corresponding to the maxima of absorption and fluorescent bands as located by microphotometric records for each material, Raman shifts have been calculated which represent both fundamental and combination frequencies. It is interesting to point out in this connexion that combination frequencies calculated in this way, when not in agreement with the values of previous workers, can still be built up either entirely with their values or jointly with our own.

The importance of this new technique for the study of Raman spectra lies in two directions. First, with the use of sunlight the time of exposure is considerably cut down, so that very faint lines can also be brought out; secondly, small shifts of faint Raman lines, which generally are masked by the strong incident spectrum, can be calculated.

Since the minute traces of potassium permanganate used to produce the absorption bands in the various substances do not seem to affect their modes of vibration concerned in the Raman effect, their action and that of didymium salts in glass may very appropriately be referred to as 'optically catalytic'. Workers on the Raman spectra of glass have also noted previously that small quantities of metallic oxides present in different varieties of glass do not alter their Raman lines.

There are other points connected with the method which throw an interesting light on the nature of the relations observed. For example, the work of Merton[2] and Taylor[3] on the absorption bands of solutions of potassium permanganate in different solvents shows that the differences of wave numbers between successive bands, for any solution, are not really constant, although their mean value is usually taken to represent the frequency of the MnO_4 ion as affected by the particular medium of the solvent. On the view taken in this paper, these discrepancies between the differences of wave numbers of the successive absorption bands are real, and are due to the fact that the actual positions of the absorption bands are conditioned by the appearance of Raman lines representing either fundamental or certain combination frequencies of the solvent medium, at certain definite wave-lengths constituting the fluorescent spectra of the substance under examination.

No results are given here as they would occupy too much space. They will be published with full experimental details elsewhere shortly.

Points from Foregoing Letters

THE first quantitative measurements of the abundances of the elements in the planetary nebulæ are derived by Mr. T. L. Page from the intensities of 'forbidden' lines in the spectra of these objects. An explanation is sought for the surprisingly high abundance of neon and argon relative to oxygen, as compared with their proportions in the composition of the earth.

A variety of radioactive bromine has been detected, by Dr. C. H. Johnson and F. T. Hamblin, which possesses a half-period of some twenty-four hours. The authors consider that it is either an activated bromine nucleus or a new isotope.

The absorption of neutrons (belonging to Fermi's group C) by boron and by cadmium at ordinary and at low temperatures has been determined by a group of investigators from the Ukrainian Physico-Technical Institute. They conclude that the absorption curve of cadmium has a selective character. The results for boron do not agree with the 'inverse velocity law', but that may be due to a deviation of the silver detector from the $1/v$ relation.

G. L. Mack writes that he has failed to confirm the increase of ascorbic acid (vitamin C) when cabbage is boiled, as reported by Guha and Pal. The amount, he says, is no greater than that obtained by alcohol extraction or after treatment with hydrogen sulphide. The author concludes that practically all the apparent increase is due to the inactivation of an oxidizing enzyme, and not to the hydrolysis of an ascorbic acid ester.

E. Baldwin and Dr. D. M. Needham find that the electrical tissue of the ray, *Torpedo*, contains enzymes analogous to those found in the muscular tissue of that fish, and also in the jaw-muscle of the sea-urchin, *Sphærechinus granularis*. They deduce that both muscle and electrical organ derive their energy from the same chemical sources and through the same chemical mechanism.

In a stock of fruit-flies with very rough eye surface, accompanied by an inversion in the X-chromosome (originally induced by X-rays), Dr. H. Grüneberg has observed the appearance of animals with normal eye surface and without chromosome inversion. This is claimed to be the first clearly demonstrated case of complete reversal of a gene rearrangement.

A. Levan reports that crosses between two strains of chive (*Allium Schœnoprasum*) containing 16 and 24 chromosomes respectively gave offspring containing mostly 16 chromosomes when the mother plant contained 16, while when the mother plant contained 24, the chromosome number in the offspring varied between 16 and 24 (except 20), the most frequent being 17.

Dr. M. Schlesinger finds that his pure bacteriophage preparations are intensively stained by Feulgen's reagent, whilst bacteria and bacterial debris treated in the same way remain unstained.

Graphs showing the relation between the Clausius Mosotti function, P (proportional to the polarizability of the molecule) and the density, the pressure and the change in kinetic energy of the internal motion of the molecules, ΔK, are given by Prof. A. Michels, C. Michels-Veraart and A. Bijl, from calculations based upon recent data for carbon dioxide. They find a nearly linear relation between the polarizability and the pressure, also between polarizability and ΔK.

Previous work of Prof. K. Prosad and D. K. Bhattacharya on didymium glass, of which the wave-lengths of absorption bands were taken as the incident exciting lines for the study of the Raman spectra of glass with very satisfactory results, has now been extended to a number of organic liquids and to nitric acid solution. Absorption bands in these liquids were produced by adding traces of potassium permanganate.

Research Items

Asianic Deities in the Paganism of Ancient Georgia

A RE-EXAMINATION of the evidence relating to Paganism in early Georgia by Prof. M. Tseretelli (*Georgica*, 1, 1) indicates the need for revision of hitherto accepted views, and the recognition of a considerable Asianic element in the ancient cults of the Caucasian area. The deities enumerated in the sources are Armaz Zaden, Ga or Gaím and the Chaldean goddess It'rujan, or It'rushana. The resemblance of Armaz to Ahura-Mazda, together with the fact that Mazdaism was introduced into Georgia long before Christianity, suggests an obvious identification. There is no doubt that Armaz is a Georgian national deity. The account of the copper idol and the religious festival of Armaz given by St. Nina point to identification with Teshub, the god of the Mitanni and Urartaeans, the pre-Indo-European people of Armenia, who is represented with thunderbolt and axe, and may be related to Zeus Labraunda and Jupiter Maximus Dolichenus, *natus ubi ferrum exoritur*, whose worship was said to have been brought to Kommagene by Khalybean smiths. The god Zaden with Armaz gives rain and fertility to the Georgian soil. He is, in fact, the Asianic god of fertility, Sandar or Marduk, the Babylonian Tamūs. The custom of offering first fruits and the first born of man and beast to Zadin is probably Semitic. Human sacrifice was also offered to Ga and Gatsi. It is argued that Gatsi and Ga are the 'father' and 'mother' of the widespread fertility cult. A deity not mentioned in the texts, the goddess Ašhara, is still worshipped among the Abkhasians. She may be the goddess Išhara, mentioned in the Boghazhoĭ texts, who was also worshipped in Babylon, Assyria and Elam. She is the tutelary goddess of the homestead, and the mountaineers still worship "the angel of the house". Finally, there is the Chaldean goddess It'rujan who is opposed to Armaz. It'ru is rightly identified with Ishtar; 'jan' is probably Samain, the goddess of heaven, who as a Chaldean deity destroyed the idol of Armaz and was resisted by the natives. There is also evidence of a tree and pillar cult.

Antiquities in Shetland

A TOUR of archæological investigation in Shetland made by Mr. Ludovic Man in July last, following up a similar investigation in Orkney last year, has produced some interesting results. An examination of the glacial clays and derived gravels produced a number of rolled stone implements of types similar to those of the palæolithic cultures of England and France. At Bressay an old land surface about three feet below the existing surface yielded more than a hundred tools, mostly of quartz and quartzite and of small dimensions, unrolled with sharp edges, which Mr. Man classifies as mesolithic. On Ward Hill at Sumburgh, a settlement of considerable size has been exposed by wind erosion. Stone foundations of a large number of buildings have been bared. The walls appear to have been three feet thick at the base, and the oval internal chamber some fifteen feet by ten feet in dimensions. No traces of superstructure survive; but stone implements, the half of a large saddle quern, and a massive hammer-stone, weighing thirty pounds, point to a considerable antiquity. Possible evidence of cultivation is found in small cleared plots, thirty feet in diameter, with the stones from the clearing lying without system on the periphery—it may be a prehistoric anticipation of the present method of cultivation in walled enclosures. The most interesting find, however, was at Braewick, where storm water had breached an 'ayr', or storm beach, and drained a small lock, exposing ancient timbers, in which the distinctive character of the nails, and the wooden pegs with hexagonal shafts, point to a Viking origin. If further examination of the material, which is now in Glasgow, confirms Mr. Man's conclusion that this is part of a Norse boat, it is the first find of that kind to be recorded in Scotland.

Fossil Horse Remains from Idaho

NORTH AMERICA has supplied in its remains of fossil horses one of the most complete of evolutionary series. The collection of bones described by C. Lewis Gazin, from the Hagerman lake beds of Idaho, belonging to the Upper Pliocene, contains an abundant assortment of remains of *Plesippus shoshonensis*, an advanced member of its genus bordering on the horse types of the Pleistocene age (*Proc. U.S. Nat. Mus.*, 83, No. 2985, 281, Washington 1936). The material included 130 skulls of the species named above, and a large quantity of other skeletal material, some of which was found still in a position of articulation. The appearances are that the remains accumulated naturally round a water-hole, for amongst the many other vertebrates which are represented in the Hagerman beds there is a noticeably large number of aquatic forms. The paper contains descriptions, measurements, and comparative comments upon the horse remains.

Urethral Sinus in Rodents and Insectivores

THE male of certain rodents and insectivores possesses a sac-like diverticulum of the urethra, the urethral sinus. The development of this structure in the white mouse and its occurrence in other forms have been dealt with by Hall (*J. Anat.*, 70, Pt. 3, 1936). The sinus makes its appearance about the sixteenth or seventeenth day. At this time, the fusion of the genital folds gives rise to the penile or secondary urethra, and the sinus arises as a dorso-lateral bulge at their point of junction, but is derived from the primary urethra. A pair of solid club-shaped structures then arise as buds from the urethral epithelium just at a point where the sinus bulge occurs; these are the rudiments of Cowper's glands, which in the adult open into the base of the urinary sinus. The walls of the sinus are similar in nature to those of the urethra, and contain glands, whereas the epithelium of the penile urethra is non-glandular. The presence of this urino-genital sinus is reported in *Evotomys glareolus*, *Microtus hirtus*, *Apodemus sylvaticus*, *Mus rattus*, *Cricetus auratus* and *Fiber* (that is, *Ondatra*) *zibethicus*. It is apparently not present in *Cavia cobaya*.

Loose Smut of Oats

THE fungus *Ustilago Avenæ*, causing loose smut of oats, is capable of infecting its host through the stigma of the flower, and the disease may also appear from later infection. A paper by Mr. Robert McKay ("Methods of Infection of Oat Grain with Ustilago Avenæ and the Influence of External Factors on the Incidence of the Disease", *Sci. Proc. Roy. Dub. Soc.*, 21, No. 33, July 1936) shows that under the conditions of the crop in Ireland, the fungus produces a resting mycelium within the glumes, and further spores may also lodge there. These remain ungerminated until the following spring. Experiments on washing flower-infected grain in water, and on removing the glumes (de-hulling), both gave a substantial reduction of infection in the subsequent crop. A combination of these two methods of treatment resulted in almost complete control of the disease, and suggests that most of the infection is brought about by the ungerminated spores lodging within the glumes.

Immunity of Apples to Woolly Aphis

IN certain countries the use of immune stocks and stems on which desirable varieties are grafted has met with considerable success as a means of combating attacks of woolly aphis (*Eriosoma Lanigerum*). An attempt to elucidate the underlying causes of resistance and immunity to this pest is described by M. B. Crane *et al.* (*J. Pom. and Hort. Sci.*, 14, 2, 137; 1936). Its life-cycle is outlined, and preliminary experiments on the physiological aspect of immunity described. These suggest that the mechanical structure of the stem and the presence of certain insoluble substances may possibly be related to resistance, though they do not explain complete immunity. A genetical analysis was made by crossing a large number of common apple varieties with a number of well-known susceptible and immune rootstock varieties and testing the resultant seedlings for resistance or immunity. The results of this analysis indicate that "the hereditary behaviour of immunity is determined by and dependent upon a certain balance of genetic factors and is governed by a number of genes, the action of which is in part complementary and in part cumulative". Several immune seedlings raised in this way are being tested for their suitability for general use in respect to vigour, ease of propagation and productivity.

Diorites of the Cascade Range, Oregon

A SERIES of dioritic intrusions penetrate Tertiary volcanic rocks in a narrow belt which extends longitudinally through the Cascade Range of Oregon. An interesting regional study of these rocks and the associated metasomatism and metamorphism has been made by A. F. Buddington and E. Callaghan (*Amer. J. Sci.*, 421–449; 1936). The intrusions are mostly dyke-like, but there are numerous plugs and a few small stocks. The rock-types represented range from augite-diorite to granodiorite and porphyritic dacite. Replacement of plagioclase by orthoclase is a common feature throughout. Similar orthoclasization, described by Gillson, transformed a gabbro into quartz-monzonite (Pioche, Nevada) and was ascribed by him to the action of potash-bearing emanations from below during the magmatic stage and also, locally, after solidification. The Cascade rocks are shown to be closely related chemically to those of the Mesozoic intrusives of the Sierra Nevada. Volcanic rocks surrounding the intrusions have been modified through zones varying in width from a few inches to nearly half a mile. In places the original rocks (basalt-andesite-rhyolite series) have been wholly reconstituted and changed to tourmaline-hornfels.

The Patwar Meteorite, 1935

IT has been estimated that the number of meteorites recovered, after their fall to the earth's surface has been actually seen, averages about four per year since the year 1850. A large proportion of these meteorites are stones or masses of crystalline rock, a much smaller proportion being composed of metallic iron alloyed with nickel and cobalt. An account of the "Patwar Meteoric Shower of 29th July, 1935", by Dr. A. L. Coulson (*Rec. Geol. Surv. India*, 69, 439), illustrates the considerable amount of careful work required to ascertain the circumstances of the fall of a meteorite, the recovery of its various parts, and the subsequent mineralogical and chemical analyses. Reports collected from the Tippera district of Bengal indicate that the Patwar meteorite fell on July 29, 1935, at $14^h\ 20^m$ Indian Standard Time. Its fall was accompanied by the usual phenomena of light and sound. Five portions of the meteorite were recovered over an area of about 4½ square miles. The largest portion, weighing 23 kgm., which came from Patwar, had penetrated the ground, presumably soft owing to monsoon conditions, to a depth of 34 inches. This portion, which is completely illustrated in the report by a number of photographs, has a greatest circumference of 2 ft. 9½ in.; its greatest length is 1 ft.; its breadth 10 in. and its thickness 8½ in. The specific gravity of the meteorite is 4·21. Analysis shows that the meteorite, which is intermediate in composition between a stone and an iron, is composed chiefly of nickel-iron, with olivine, enstatite and bytownite, together with smaller amounts of other compounds including hydrocarbons.

Absorption of Short X-rays

T. R. Cuykendall and M. T. Jones have recently described (*Phys. Rev.*, 50, 105) absorption experiments on X-rays from a 600 k.v. tube. A double crystal spectrometer was used to isolate X-ray beams of wave-length down to 40 X.U. The absorption of very short X-rays by carbon was in excellent agreement with the Klein-Nishina scattering formula. The absorption coefficients for a number of elements, heavy and light, were determined, and the photo-electric part of the absorption fitted to an empirical formula. The photo-electric absorption observed in lead in this frequency region is about 10 per cent higher than that calculated theoretically by Hulme and others.

Mass-spectrographs

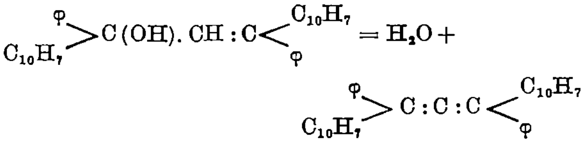
IN an article on "Second Order Focusing for Mass Spectrographs" (*Proc. Camb. Phil. Soc.*, 32, pt. 3) Mr. W. W. Sawyer considers the conditions under which focusing may be improved when, instead of the electrostatic deviation being produced by the field between parallel plates, the field between co-axial cylindrical plates with the axis perpendicular to the plane traversed by the charged particles is substituted. The mean path of the particles in this field is nearly a concentric circle, and on emergence they enter a magnetic field the lines of which are parallel to the axis of the cylinders and the section of which is a circle. The advantages of this arrangement were mentioned by Dr. F. W. Aston in a recent note in NATURE (137, 357 ; 1936). Mr. Sawyer gives the dimensions of the spectrograph constructed on these lines as follows : mean radius of cylinders 40 cm. ; angle subtended at the axis ½ radian ; distance from farther edge of electrostatic to near edge of magnetic field 15 cm. ; diameter of magnetic field 15 cm. ; the near edge of the photographic plate is 11·3 cm. beyond the farther edge of the magnetic field and 16·2 cm. from the axis of the beam between the two fields ; and the plate itself is inclined at 24° to this axis.

Resolution of an Allene Compound

THE prediction that optical activity could be exhibited by allenes of the general type

$$ {}^{a}_{b}\!>\!C = C = C\!<\!{}^{c}_{d} $$

was made by van't Hoff in 1875 ("La Chimie dans l'Espace", p. 29) and many unsuccessful attempts were made to verify it. The linking of the central carbon atom in the triad differs considerably from those types for which the tetrahedral theory has been shown to hold. The groups a and c and b and d may be identical. P. M. Raitland and W. H. Mills (*J. Chem. Soc.*, 987 ; 1936) have now shown that the compound in which $a = d = C_6H_5 = \varphi$ (phenyl) and $b = c = C_{10}H_7$ (naphthyl), when produced by the catalytic dehydration of the alcohol :



$$ {}^{\varphi}_{C_{10}H_7}\!>\!C(OH).CH:C\!<\!{}^{C_{10}H_7}_{\varphi} = H_2O + {}^{\varphi}_{C_{10}H_7}\!>\!C:C:C\!<\!{}^{C_{10}H_7}_{\varphi} $$

by means of optically active catalysts, can be obtained in two entiomorphous forms. As catalysts, *d*- and *l*-camphor sulphonic acids were used in benzene solution. The specific rotation $[\alpha]_{5461}$ of the active allene has the large value of 437°–438°. The two forms (m.p. 158°–159°) combined in solution in ether to a racemic compound (m.p. 242°–244°). Van't Hoff's prediction of the enantiomorphism of unsymmetrically substituted allenes is thus verified. It depends on the assumptions of the linear arrangement of the three carbon atoms and the disposition of the external valencies of the terminal carbon atoms in planes at right angles to one another.

The Marconi-E.M.I. Television System

ON the occasion of the recent demonstrations of television provided in connexion with the Radio Exhibition at Olympia, the programmes were transmitted on alternate days by the Baird system and by the Marconi-E.M.I. system. Some details of the latter system are given in an illustrated pamphlet just issued by the Marconi-E.M.I. Television Co., Ltd. The system employs one or more 'Emitron' scanning cameras, having no moving parts, by means of which the scenes to be transmitted are directly and continuously transformed into electrical impulses without the intermediary of a film device. These cameras can be used under normal conditions of daylight on exterior locations or in studios. Film scanning cameras are also included in the normal equipment. In either case, the resulting electrical impulses are fed to a specially developed modulator unit, whence the oscillations of the main transmitter are controlled. A suitable synchronizing signal is included in the transmissions by means of which complete steadiness of the received picture is ensured. The pictures are transmitted at a frequency of 25 per second with a scanning detail of 405, 240 or 120 lines, and provision is made in the equipment for either straight or interlaced scanning. The latter system is recommended since flicker of the received picture is entirely eliminated. The radio transmitter consists essentially of a master oscillator, frequency doubler and amplifying and modulating equipment. With the carrier frequency in the region of 40 megacycles per second, it is claimed that the frequency can be maintained constant to an accuracy of ±1 part in 20,000. The modulating stages are designed to have linear response from zero frequency up to 3 megacycles per second. The aerial system comprises a number of aerial and reflector units suspended round the periphery of an octagon ; the whole system is designed to give maximum radiation in the horizontal plane, uniform in all directions. In the arrangement of the aerial system at the B.B.C. station at Alexandra Palace, the aerials for the sound and vision transmissions are erected one above the other on the same tower.

Accuracy of Meteor Observations

WITHIN recent months, three independent articles have appeared in different journals dealing with this subject. Mr. B. S. Whitney has published (*Mon. Not R.A.S.*, 96, 5, March 1936) an interesting paper, "New Methods for Computing Meteor Heights", in which it is admitted that meteor heights deduced from ordinary visual observations are subject to large errors because of the difficulty in observing and plotting the paths accurately. He proceeds to develop a method for adjusting the beginning and ending as seen at different stations, the adjustments being the smallest possible which will refer the recorded directions to a common point. In the case of multiply observed meteors or fireballs a least square solution is developed, and three cases have been already computed by the method by the staff of Flower Observatory of the University of Pennsylvania, where the author is engaged in research. Unfortunately, the numerical results are not given, so it is impossible to judge the extent of the observational errors. In *Popular Astronomy* of May 1936 there is an article by Messrs. F. Watson, jun., and E. M. Cook, entitled "The Accuracy of Observations by Inexperienced Meteor Observers", in which some rather startling conclusions are drawn from the results of observational tests. It appears that in the case of inexperienced observers, the probable error in the direction of a meteor lies between ± 10·8° and ± 18·8°. Experienced observers, however, concentrating on bright meteors, have reported observational errors as low as ± 4°. The Rev. Dr. M. Davidson (*J. Brit. Ast. Assoc.*, 46, 8, June 1936) has given a very comprehensive analysis of the method which he proposes for computing real paths, assuming the *direction* of flight to be accurately recorded, but allowing for the beginning or ending of the apparent path to be missed. In this article, "The Computation of the Real Paths of Meteors", two numerical examples are fully worked out, and it is shown that in both cases a considerable portion of the flight was missed by one or other observer. These papers suggest that the whole subject of meteor observation may require reconsideration in order that more accurate results may be obtained.

Science and Electric Lighting

A POPULAR discourse at the Blackpool meeting of the British Association was given on Friday, September 11, by Mr. C. C. Paterson. He chose as his subject "Science and Electric Lighting", and illustrated his discourse by many striking and spectacular experiments. Through the medium of these experiments, he enabled the audience to picture the present outlook of the scientific worker in the field of electric lighting and how rapidly it is changing. During the last four years, the amount of light that can be obtained from a given quantity of electricity has been increased three times. During this time, it has also been demonstrated that it is possible to make lamps of which the luminous component is at least a hundred times brighter than the brightest filament previously available. These great achievements are rapidly being exploited by industry in Great Britain.

Mr. Paterson began by showing the fundamentally different methods of producing electric light by filament lamps and discharge lamps. In one we obtain light from solids and in the other from vapours. In the latter kind of lamp, the light comes from vapour made brilliantly luminous by passing electricity through it. He showed a lamp with a container for a small quantity of vapour having a volume of about a twentieth of a cubic inch. Success followed research when it was found how to pass a current through this little enclosure. The difficulty was to make the free molecules of the vapour carry electricity, but once the current started it was difficult to control it. The intensity of the light in this lamp is a measure of the vigour with which the molecules of vapour respond to the stimulation. The molecules of different vapours respond in different ways, and they show their peculiarities by the nature of the light they emit. By the spectrograph, this light can be separated into its various components, and from the point of view of the lamp maker these specify the lamp.

In the incandescent filament lamp, the filament, of which is now made of tungsten, and is heated to a very high temperature, the molecules of the solid tungsten do not radiate light in the same way as vapour molecules. This is shown by the fact that the spectrum of this lamp contains all the colours shaded into one another. The spectrum of any incandescent solid or liquid is always of this type. This follows because the molecules cannot move as if they were in free space ; they are constrained by the neighbouring molecules. Their light is very similar to that of the sun, which comes from incandescent gases and vapours under extreme conditions of pressure. The light given by an incandescent filament being a rough imitation of sunlight satisfies our demands for illumination. Why therefore should we want to use something else ? The reason is that the new lamps are able to give us much more light in comparison with the waste heat that is always produced.

With filament lamps the higher their temperature the more light they give, but the tungsten evaporates more rapidly the higher the temperature and thus its life is short. Research has discovered that if we coil the filament so that it occupies less space, the total convection currents will be less and the evaporation will be reduced. From this was developed the tightly coiled gas filament lamp which has been the most popular type of electric lamp for the last twenty years. In addition, by coiling the coil the efficiency can be still further increased. More than half the number of lamps now used in Great Britain for domestic purposes have coiled coil filaments and they give up to twenty per cent more light for the same consumption of electricity.

The metal tungsten out of which the filament is made is one of the toughest and most refractory of metals. It is so hard that it has to be drawn through diamond dies which have to be pierced with round holes no more than the size of a fine human hair. The wire diameter has to be correct to within 0·5 per cent, that is, five millionths of an inch. The craftsmanship of the girls who do this wire drawing is deserving of the highest praise. Mr. Paterson said that one of them described the process to him as like threading a wire you can't see through a hole that isn't there. This minute thread has then to be coiled with the greatest uniformity and equal precision, and finally the coil has to be again coiled. Out of the 3,775 turns in this spiral, not a single one must touch its neighbour, although the space between them is less than the thickness of a cigarette paper.

The enhanced efficiency of a vapour lamp is due to the absence of unwanted kinds of radiant rays. For mercury vapour lamps the effective light radiated is about three times as great for the same consumption of energy. If we had two electric lamps both using a pennyworth of electricity a day, but one giving only blue light and the other only green light, the latter appears to give more light than the former. The reason is that the green light is more useful to see with—in other words, it appears brighter. For this statement to be strictly correct, it has been presupposed that the blue light and the green light demand the same proportion of the electric power to produce them.

Tubular lamps were shown containing vapours of many kinds, and the difficulties of producing light of a satisfactory colour at a cheap rate were considered. The sodium lamp, which is the most economical, gives light of an unpleasing colour, and unfortunately no good way of correcting this colour defect has yet been invented. The neon lamp has been found very useful for floodlighting red brick buildings and for other colour effects. It is almost completely deficient in green and blue rays.

Mr. Paterson mentioned that some new investigations have opened out a new and very promising field of research. It has been discovered that if we coat the inside of a neon tube with a certain luminescent powder, the activity of the gas in the tube excites the characteristic fluorescence of this powder. It therefore gives out light of the colour we want, which, as it mixes with the red light from the neon gas, gives a series of pleasant colours very suitable for interior lighting. Hitherto it has only been found possible to excite fluorescence to an appreciable extent by direct excitation of the powder by the electrons of which the current consists, or else by means of the mercury discharge, which is very rich in ultra-violet lines. The great advance lies in the discovery that neon, which is comparatively poor in ultra-violet light, can by using suitable powders be made to excite luminescence. These luminescent materials will probably be largely used in electric discharge lamp lighting. They will add the missing colours to light given out by vapours and gases, thus making objects illuminated by them appear as they do in daylight.

It was found four years ago that very great yields of light could be obtained from the passage of electricity through mercury vapour, if the pressure of the vapour was increased to about one atmosphere instead of using only one hundredth of an atmosphere as in the older types of lamp. This has led to the improved lighting of hundreds of miles of streets in Britain. There are now about 15,000 street lighting posts fitted with these lamps.

Light is becoming so cheap that it is foolish not to make full use of it. Its liberal use contributes greatly to safety. It enhances the beauty of our homes and increases the efficiency of our workshops. Gardens and highways at night can be made beautiful by its use. Blackpool, perhaps more than any other town, has improved its amenities by using artificial light. Incidentally, this gives a royal welcome to its visitors.

Plant Hunting and Exploration in Tibet

THE second evening discourse at the Blackpool meeting of the British Association was delivered on September 15 by Capt. F. Kingdon-Ward. He said that however much we may regret some of the results of the industrialization of Britain—the destruction of forest, the urbanization of pasture land, slums, and so on—our country is in some respects a vast improvement on the England of four centuries ago. It was then a colourless land, especially during the winter. Thanks to the great interest taken in horticulture and sylviculture to-day, it is that no longer. About twelve thousand species of introduced trees, shrubs and herbs are cultivated in the open—nearly ten times the total number of flowering plants which occur wild. Thus the British climate must be singularly elastic, and the plants themselves highly adaptable. Probably in no other country in the world of equal area can so many alien plants be grown. Some are difficult, but more are easy, and not a few naturalize themselves.

Tibet, the highest plateau in the world, is not as is generally supposed a complete desert. There is a gradual increase in the flora from west to east, and from north to south, corresponding with the change in the physiographical nature of the country; the vegetation slowly changes from tundra to scrub and grassland, and from scrub to forest. Naturally, the most prolific and varied flora is found in the forested south-eastern region. This flora is a mixed one. The climate varies greatly from warm temperate at the bottom of the gorges where Tibet reaches its lowest altitude at 5,000 feet, to subarctic on the high snow-clad ranges the peaks of which attain 25,000 feet. All adjacent regions—China, Indo-Malaya, the Himalaya—have contributed to the flora of Tibet. Not every plant found there is hardy in Britain, but a surprising number are. Nor is it possible to forecast whether a given plant will be hardy or not; experience enables one to make a shrewd guess, but no more. On the whole, the plants which have proved most adaptable to our gardens are those which are not found growing under extreme conditions; that is to say, the plants, not of the tundra, nor of the deep forested river gorges, nor of the highest alpine ranges, but those of the intermediate scrub-clad plateau country, at 10,000–12,000 feet altitude.

Throughout the summer, one is busy collecting plants in flower. In late autumn, one starts harvesting seeds. It is not necessary to mark the plants when in flower, of which seed is required. Most plants are found over extensive areas where the climatic conditions are similar, and constant practise enables one to recognize a given plant by its fruits as readily as by its flowers. Particular plants occur in prodigious numbers; most species are at least common; the difficulty is to discover a rare plant! Capt. Kingdon-Ward said that he could recall very few of which he discovered but *one* specimen—*Leycesteria crocothyrros* is one of them.

Tibet has become famous as the land of the blue poppy (*Meconopsis betonicifolia*) and the scarlet creeping rhododendron (*R. repens*). But it is equally the home of many other beautiful flowers, as gentians, lilies, barberries, primulas and many more.

Science at the International Peace Congress

SCIENTIFIC concern for the preservation of world peace found abundant expression at the International Peace Congress held at Brussels on September 3–6. Special commissions considered the bearing of art, science and letters, medicine, agriculture and education on the problems of peace and war, the report of the Science Sub-Commission, formed by a small but internationally representative body of scientific workers under the chairmanship of Dr. J. D. Bernal of Cambridge, being typical of the constructive attitude of the professional delegates.

This committee clearly recognized the effects of war in disintegrating the humane purpose and international character of science, and declared that scientific workers should do their utmost to strengthen international amity not only by a general determination to oppose war but also by definite practical activity. "We have to consider," it decided, "how we can best assist in preventing an immediate outbreak of war, and in permanently removing its fundamental causes. The International Peace Campaign offers us the great opportunity of working effectively for both these ends." Stressing the importance of the radical approach, it added that scientific workers should co-operate "in the task of removing the causes of war by subjecting them to scientific and historical analyses and by exposing the theories of those who strive to excuse and justify war."

It was unanimously agreed, therefore, that a permanent Science Commission of the International Peace Campaign should be set up "with the general object of uniting all scientists in the struggle for peace". Its proposed activities include (1) the co-ordination of the work of the existing peace organizations of scientific workers and their extension to countries in which they do not exist; (2) the formation of joint commissions on (*a*) science and war and (*b*) the removal of the basic causes of war; (3) propaganda for a peace oath by all scientific workers and the incorporation of such a declaration in the oaths of those taking university degrees and diplomas; (4) concrete support for those scientific workers who are made to suffer for refusing to take part in research or other activities concerned with war.

The joint commission on science and war is to include chemists, physicists, engineers, aeroplane technicians, doctors, bacteriologists, geologists and military experts, who will endeavour (1) to study the technique of modern warfare and its probable effects on the military and civil populations; (2) to co-operate effectively in the international suppression of chemical and biological warfare; (3) to publish the results of its investigations promptly and clearly, without minimizing or exaggerating the dangers of modern war or seeking to claim an unobtainable accuracy; (4) to issue critical bibliographies on the technique of warfare and other special studies on this subject; (5) to impress on scientific workers themselves the part they are playing, directly or indirectly, in preparations for war, and to direct attention to the utilization for military purposes of funds intended for civil research and development; (6) to serve as an information bureau on technical military questions to all peace organizations.

The committee concerned with the fundamental causes of war is to include biologists, psychologists, anthropologists, medical men, sociologists, historians and economists, whose immediate task it will be to produce a concise statement on the causes of war and the ways in which men of science can help to eliminate them. It will also neglect no opportunity to expose pseudo-scientific and pseudo-historical theories used for war propaganda, such as those which postulate the biological necessity of war, the need for colonial expansion because of population pressure, the innate inequality of races, the degenerating effects of miscegenation, and so on. The regular work of this committee will therefore include (1) continuous propaganda in the scientific and popular press; (2) the exposure of subtle and direct war propaganda in schools and colleges; (3) appeals to learned societies and other organizations to defend scientific truth against distortion and unjustified rationalization; (4) the provision of study facilities by the publication of critical bibliographies and such other assistance as a central bureau can provide.

The translation of these objectives into effective practice will require considerable funds, organizational ability and individual support, but the success of the Peace Congress as a whole, combined with other evidence of a widespread appreciation of the duty and purpose of scientific endeavour, suggests that these essentials will not be lacking. They must not be if the lust for war is to be overcome by an organized will for peace. CEDRIC DOVER.

Molluscs of Northern Asia

MR. ALAN MOZLEY, after several studies of the Mollusca of Canada, has recently made expeditions into Siberia and northern Kazakstan during the open seasons of the years 1932 and 1933, when typical areas in several of the great natural regions were examined in some detail, and extensive collections made with the object of obtaining fresh and accurate information regarding the constitution and distribution of the molluscan fauna ("The Freshwater and Terrestrial Mollusca of Northern Asia". *Trans. Roy. Soc. Edin.*, 58, Part 3 (No. 24), 1935–36). The area covered includes the greater part of continental Asia to the north of latitude 50°, not including Outer Mongolia and Manchuria.

The aquatic species inhabit three types of water—ponds, lakes and streams. Of these the ponds and pond-like lakes only have an abundant molluscan fauna, and these are mostly hardy northern European species. Both the large lakes, which are uncommon, and the streams, usually present special conditions unfavourable to the molluscs. There is found to be a small group of circumboreal, a large number of Eurasian species, a few which are common to North America and north-eastern Asia, and several endemic forms. On the basis of these groups, Northern Asia may be divided into four faunal regions, the Great Siberian Region, the Baikal Region, the Far Eastern Region and the Chuckchee-Kamchatka Region.

In the northern part of Kazakstan and Southern Siberia there are numerous drainage basins in which the reservoirs are saline to a varying degree, the main salts being chlorides and sulphates which are detrimental to the molluscs. The presence of old shore lines round many of these indicates their greater extent during previous pluvial periods, fossil molluscs being found in some of these old shore-line deposits, in some cases the number of species decreasing in the descending series of beaches, giving evidence of a progressive decrease in molluscs. The species most tolerant of these conditions are *Planorbis planorbis* L., *Limnæa palustris saiidalensis* Mozley, and *Limnæa palustris Kazakensis* Mozley.

Temporary ponds formed by melting snow in spring are characteristic habitats in the steppe and forest steppe region both in Canada and Siberia, conditions of life being severe; but numbers of invertebrates manage to exist in them, including five species of molluscs in Northern Asia.

Educational Topics and Events

Cambridge.—The Vice-Chancellor gives notice that the professorship of animal pathology will be vacated on September 30 by the resignation of Prof. J. B. Buxton.

The Board of Managers of the Frank Edward Elmore Fund have awarded studentships to A. C. E. Cole of Trinity College, G. D. Hadley of Clare College, L. C. Martin of Gonville and Caius College and B. McArdale. Dr. H. G. Booker of Christ's College has been appointed assistant lecturer in mathematics, and Mrs. J. V. Robinson of Girton College assistant lecturer in economics and politics.

Dr. T. S. Hele has resigned his University lectureship in biochemistry, H. W. Hall of St. John's College, W. A. Fell of Sidney Sussex and R. S. Handley of Gonville and Caius College their demonstratorships in anatomy, Dr. M. Born his lectureship in mathematics and T. C. Nicholas of Trinity College his lectureship in geology.

Courses in administration have hitherto been specialized or restricted to different fields of administration, such as industrial, business, public, military, colonial and agricultural administration and often with more emphasis on the adjective than the noun. In a recently issued prospectus, Mr. W. R. Dunlop gives a syllabus of a course in administration with no particular applicational bias, though permitting of such bias by the appropriate selection of illustrative cases and problems. The course embodies the principles and technique, the underlying subjects and the mental activity and art common to all administration. Special attention is given to the history of administration from early times and with special reference to policy and leadership. Administration in its wider sense of human purpose and method is held to be one of the primary objectives of general education, and Mr. Dunlop would like to see specific education for administration, or at least management, made part of our educational system. The prospectus is supplemented by appendixes describing the research work, connexions and experience on which these views and the course itself are based. Copies may be obtained on application in writing to Mr. W. R. Dunlop, 57 Gordon Square, London, W.C.1.

Dr. Roscoe Pound, dean of the Faculty of Law of Harvard University, spoke recently at a Graduate School Convocation in Brown University on "The Place of Higher Learning in American Life". The general tenor of Dr. Pound's thoughtful and stimulating address (*School and Society*, August 8) may be inferred from his remark that his topic might well have had for its title "Higher Learning as Insurance of American Institutions" coupled with his opinion that what is significant in those institutions is that they tend to safeguard opportunity for all, freedom, and the corollary of freedom, responsibility. One of the points he makes is in connexion with the enormous development in recent times of means of manipulating public opinion. "The methods of advertising, carried to the limits of psychological effectiveness in business, have been taken over into public affairs. . . . Even newspapers are being left behind by broadcasting. A proper functioning of democratic institutions calls for corresponding development of the means of resistance to this pressure, and the best guarantee of intelligent resistance is to be found in a general high level of learning".

Salesmanship has long been recognized as a suitable subject of instruction in institutions of higher education in the United States. Recently the complementary science and art of shopping have received a good deal of attention, partly because the industrial depression has focused attention more urgently on the problem of how to get the most one can for one's dollar. At four regional conferences on home-economics education called by the United States Office of Education in 1934, this matter was a principal topic of discussion, and on the basis of material resulting from these and later conferences a pamphlet was prepared by specialists of that Office and published under the title "Consumer-buying in the Educational Program for Home-making : Suggestions for Teachers of Home-making in Secondary School and Adult Classes". Among the reasons given for education for buying are the enormous increase in the variety of commodities and services offered and the fact that price has become even less a guide to quality than it was formerly. The United States Government has been zealous in publishing masses of statistics bearing on the subject in the interest of consumers. Among them are numerous publications of the Department of Agriculture, including its food and drug administration. Such is the profusion of data that in July 1934 a special index to them was published under the title "Government Publications of Use to Consumers".

Science News a Century Ago

Lyell and Mantell

In a letter to Mantell written on September 19, 1836, Lyell referred to John Fleming (1785–1857), the Presbyterian minister and naturalist, who "after several applications in vain for chairs more consistent with his zoological and botanical acquirements", had accepted the chair of natural philosophy at Aberdeen. This appointment, Lyell said, had given him no doubt "much fag to get up arrears of mathematical knowledge. But unfortunately, something worse than the lectures fell to his hard fate. Several University bills and a Royal Visitation caused tremendous secretarian or clerk's labour to fall on the Junior Professor who is obliged to serve as secretary to the University."

"You will see by this that you, my good friend," Lyell continued, "are not singular in finding it difficult to gratify your liberal thirst for science, without interfering with professional profits. Really, as Milman says, it would be well for the country if, instead of abolishing prebendal stalls, they were given to clerical and lay cultivators of literature and science, who had shown that they would devote energy and superior talents to those departments. When Babbage was taunted one day by a Conservative with 'What do you mean to be when the revolution comes ?' he said, 'Lay Archbishop of Winchester'."

Association of German Naturalists

The annual gathering of the Association of German Naturalists—a society which was a forerunner of the British Association—was held at Jena on September 20–26, 1836. The meeting was attended by many civil and military officials, representatives from Great Britain, Russia, Belgium, Holland, Switzerland, Greece and Mexico, and many of the greatest German men of science, including von Humboldt, von Buch, Ehrenberg, Weber, Hansen, Reichenbach, Fuchs and Döbereiner.

At the first general meeting, Dr. Kieser, after alluding to the philosophers and naturalists Jena had produced, gave a sketch of the history of the Association. Fifteen years previously, he said, it consisted of only thirteen persons, in 1835 it numbered 500 members and attracted friends from all parts of Europe and even from the other side of the Atlantic. In imitation of the Association, others had been established in England, France, the Netherlands and America. At the same meeting Mädler described the structure of the moon and exhibited his map of its surface.

There were three other general meetings, while papers were read to the seven sections: (1) Physico-Chemical Science; (2) Geology, Geography and Mineralogy; (3) Pharmacy; (4) Botany; (5) Anatomy, Physiology and Zoology; (6) Medical, Surgical and Obstetric Science; and (7) Technology and Agriculture. On September 24, the visitors and members were presented to the Grand Duke of Saxe Weimar, and after dining with him and other princes in the Orangery, repaired to the theatre, where Goethe's "Tasso" and Schiller's "Bell" were performed.

Andrew Crosse and his Electrical Experiments

At the British Association meeting in Bristol in 1836, no communication raised more enthusiasm than the account given by Andrew Crosse (1784–1855) of his experiments on electric currents and their effects on minerals. Crosse was a man of means who lived at Broomfield on the Quantock Hills, Somerset, and at Bristol he gave a general invitation for any present at the meeting to visit him. The first to do so was Sir Richard Phillips (1767–1840), who described his visit in a letter to Mantell which was read at a conversazione of the Mantellian Museum at Brighton on September 20. The account was afterwards published in Sturgeon's *Annals*. Sir Richard spoke of the fine house and park and also of the music room in which were seven or eight tables filled with batteries. "They resembled battalions of soldiers in exact rank and file and seemed innumerable. Altogether there were 1,500 voltaic pairs at work in this great room, and in other rooms about 500 more. There were besides, other 500 ready for new experiments". But Crosse's "greatest electrical curiosity was his apparatus for measuring, collecting and operating with atmospheric electricity. He collects it by wires, the 16th of an inch diameter extended from poles to poles, or from trees to trees in his grounds and park".

Walter Hancock's Steam Carriages

In the *Mechanics' Magazine* of September 24, 1836, is an account by Hancock of the work done by his steam carriages *Infant*, *Erin*, *Enterprise* and *Automaton* in London. He said that altogether these carriages had run about 4,200 miles, carried 12,761 passengers, made 525 journeys between the City and Islington, 143 between the City and Paddington and 44 between the City and Stratford. They had used some 55 chaldrons of coke. The same issue of the *Mechanics' Magazine* contained a description of the *Automaton*, the last of the four carriages to be built.

Societies and Academies

Paris

Academy of Sciences, July 27 (*C.R.*, 203, 289–352).

Aymar de La Baume Pluvinel: Obituary of Paul Stroobant.

J. Geronimus: Some orthogonal polynomials.

Georges Giraud: Complement to a result on equations with principal integrals.

Kyrille Popoff: The pendular movement of projectiles.

Emile Merlin: A particular case of trajectories of certain heterogeneous perfect fluids.

Assène Datzeff: A transformation which keeps the form of canonical equations.

Raymond Chevallier and Marcel Laporte: The permanent magnetization of steel in the neighbourhood of a circuit traversed by a rapid aperiodic discharge.

Louis Néel: The theory of constant paramagnetism. The application to manganese.

G. Foex and Ch. Fehrenbach: Variations of the magnetic moment of the cobalt ion in the anhydrous chloride and in the systems of mixed crystals $CoCl_2$–$CdCl_2$ and $CoCl_2$–$MnCl_2$.

Mme. Marie Freymann, René Freymann and Paul Rumpf: The absorption spectra in the near infra-red of aniline derivatives.

Roger Servant: A spectro-polarimeter for the Schumann region.

Léon Capdecomme: The influences of elliptic light and of the orientation of the polarizer in comparisons of reflecting powers with the microscope.

Pierre Brun: The formation of metallic alcoholates.

Henri Muraour and Albert Michel Lévy: The spectrum of ionized calcium obtained by collisions with detonation waves.

André Kling and Maurice Claraz: The rapid determination of oxygen in gaseous atmospheres.

Jean Byé: Study of molybdic chlorhydrin and of the normal molybdate of glycol.

Charles Bedel: The minimum temperature of oxidation of silicon. The lowest temperature at which the oxidation of silicon commences is relatively high: it is lowered by the presence of moisture.

Mlle. Denise Montagnon: Contribution to the study of the double iodides of copper and ammonium.

Charles Dufraisse, Léon Velluz and Mme. Léon Velluz: Dissociable organic oxides. Special study of 9-phenylanthracene and of some of its derivatives.

Roger Perrot: Some nitrosochlorides of the benzene series.

Mlles. Marthe Montagne and Yvonne Isambert: The action of ethylmagnesium bromide on butyric ethylanilide.

Martin Battegay and Pierre Bœhler: α- and β-mononitroanthracene.

André Meyer and Paul Heimann: The nitroso derivative of 4-hydroxycarbostyril.

Georges Lévy: The nitration of β-ethylnaphthalene. The synthesis of 2-ethyl-8-naphthol.

Gonzague Dubar and Mlle. Dorothée Le Maitre: New deposits of Spongiomorphides and of Algæ in the Lias and the Bajocian of Morocco.

Charles Bois: Deep focus earthquakes.

Achille Urbain and R. Cahen: The proportion of derivatives of degradation of nitrogen in the serum of some ungulates.

René Legroux: The treatment of glanders in the Equideæ.

Georges Bourguignon and **Marcel Monnier**: The variations of chronaxy under the influence of coloured light in spasmodic stiff neck.

Baruch Samuel Levin and **Ivo Lominski**: Vaccination against bird plague with virus treated with X-rays.

Melbourne

Royal Society of Victoria, July 9.

L. W. **Stach**: An Upper Oligocene bryozoan faunule. A small faunule at 66–67 feet in the Torquay bore is indicative of shallow water deposition. The range of *Cellaria depressa* is extended to Upper Oligocene, and a study of *Otionella cupola spiralis* Chapman suggests that *Cupuladria* Canu and Bassler is a synonym of *Heliodoma* Calvet. *Cucullipora tetrasticha* belongs to sub-family Hippoporininæ of Schizoporellidæ.

F. **Chapman** and W. J. **Parr**: A suggested classification of the Foraminifera. The classification differs from Cushman's in the grouping of the arenaceous after the hyaline types. The whole order (Foraminifera) is arranged in the super-families, the Allogromoidea (chitinous), the Spirillinoidea (hyaline or perforate types), and the Ammodiscoidea (arenaceous, porcellanous and subarenaceous forms). The family groups of Cushman are re-sorted and reduced from 47 to 33. About 570 genera are admitted up to the year 1934, as against 144 genera in Chapman's "Foraminifera" of 1902.

G. W. **Leeper**, **Ann Nicholls** and S. M. **Wadham**: Soil and pasture studies in the Mount Gellibrand area, Western District of Victoria. A soil survey of 12,000 acres of pastoral country surrounding the volcanic cone of Mount Gellibrand. Nine soil formations are defined with laboratory analyses of each type, and mineralogical studies of the fine sand fractions. The present flora is described, and future development of the area discussed.

B. J. **Grieve**: The application of a staining and maceration method in tracing the distribution of bacteria in wood vessels of herbaceous plants.

Moscow

Academy of Sciences (*C.R.*, 2, No. 4, 1936).

G. **Sirvint**: Asymptotic series of Dirichlet.

L. **Vinokurov** and E. **Levshin**: Study of the extinction of luminescence of phosphorescent substances activated by organic activators.

G. G. **Laemmlein**: Model of polymerized molecule of silicic acid in molten flow.

M. N. **Michailova** and M. B. **Neumann**: The cetene scale and the induction period preceding the spontaneous ignition of Diesel fuels in bombs.

S. J. **Krajevoj**: The influence of ultra-short rays on the chromosomes of plants.

O. **Istomina** and E. **Ostrovskij**: The effect of ultra-sonic vibrations on plant development.

A. N. **Klechetov**: New species of *Colletotrichum* on the rubber-producing plant *Taraxacum kok-saghyz* Rodin.

A. **Sergejev**: The influence of human structures on the distribution of birds in steppes.

Forthcoming Events

Tuesday, September 22

Engineers' Study Group on Economics, at 6.30.—Annual General Meeting to be held at 23 Grosvenor Place, London, S.W.1.

Faraday Society, September 24–26.—General Discussion on "Structure and Molecular Forces in (*a*) Pure Liquids and (*b*) Solutions" to be held in the University of Edinburgh.

Human Tendencies

IN the annals of the British Association there will be found not one but many landmarks in the history of science. The Blackpool meeting of 1936, it is probable, will stand out as a whole, certainly in popular memory, as the one meeting above all others which from the inception of the Association up to that date has endeavoured to address itself on a united front to a diagnosis of the current ills of human society. The presidential address, no less remarkable for its controlled imagination than for its keen insight into and power of analysis of complex social phenomena, set the keynote of the meeting; and it was a striking testimony to the sense of responsibility to the community which is felt by the men of science of to-day that the lead given by the president of the Association was followed not alone by the sections dealing with the biological and humanistic sciences. Even a branch of study so academic, so apparently remote from the stress of current social problems as palæontology, afforded Prof. H. L. Hawkins in the presidential address to Section C (Geology), part of which appears in this issue of NATURE (p. 534), the material for pungent comment on current tendencies in human development.

It is possible, however, that on reflection there may appear no paradox in the fact that a science such as palæontology, of which the data are far removed from current events, should nevertheless provide a canon of criticism for tendencies of to-day. Although we may feel inclined to qualify Prof. Hawkins's dictum that our knowledge of the ancient Romans is at best equal to our knowledge of the trilobites, yet we may agree that as we can here view the beginnings, the prime, and the decay of long extinct species more clearly and more objectively than we can observe the rise and decline of the powers and empires of the past, so we may perhaps deduce from them more certainly the operation of biological laws which affect the evolutionary process in human affairs, no less than those which govern that process in the development of man himself.

Prof. Hawkins led his audience from stage to stage of evolution in organisms of the past to the emergence of man himself. It might seem a sorry commentary on his text for those who believe in the evolutionary process as a progression in perfectability to turn to the discussions and addresses in other sections, and to see what man has made of himself in the vast interval of time which has elapsed since that first emergence. There they would have found that man of to-day was being brought to the bar of judgment for handling the dangerous instruments of which scientific development has given him control with the mentality of a schoolboy, and as Lord Horder pointed out in the discussion on "The Strain of Modern Civilization", indicted as the subject of neuroses and auto-infection, because he has allowed himself to fall a victim to the organization which he himself has built up (see p. 529).

It is unfortunate that on the anthropocentric view imposed upon us by the condition of our being, the evidence of palæontology as an objective standard of progress should cease to be operative with the coming of man. When once man as such has evolved, palæontology can tell us little further of really fundamental and significant organic change. Unless mere size of brain be the criterion —in which event man may have surmounted the peak of his development with the passing of Neanderthal man, and modern man actually represent the entry on a phase of decline—on the coming of the modern man with his more highly convoluted brain, that page of evolution is closed, in any event for the present, whatever the future may hold. From that point onward, throughout man's strenuous struggle to build up civilization, the evidence of change in man is indirect—and neither palæontology, archæology nor, except to a limited degree, history tells us what functional change may have accompanied his further development. Man as we see *ex post facto*, at the time of his emergence, is differentiated from his contemporaries of the animal world by the spirit, and by its achievement he should be judged. Less well equipped than any other animal approaching him in size with either protective covering or strength of tooth and claw, yet he is less at the mercy of his environment. Armed with the most powerful weapon of defence and destruction that Nature has forged, the human brain, he has conquered his environment so that not only has this otherwise defenceless creature made himself master of every quarter of the globe, irrespective of climatic and other environmental conditions, but also he is exterminating or subjugating all animal life, while exploiting all natural resources as well as conquering the air and drawing treasure from the depths of the sea. Hence man's progress in fact is commonly measured by his control of the material resources of the world.

It is scarcely necessary to stress the point to which this assessment of human progress in materialistic terms has brought us. A century of expansion and, on the whole, uninterrupted advance in every department of civilized life has now received a check. A prolonged period of economic depression and disturbed political conditions, international as well as in some instances internal, has dislocated what had come to be regarded as the normal flow of life, and has induced a wave of pessimism, which questions the values of what has hitherto been regarded as progress. Even the very fact whether man has progressed at all, at least since the early days of his emergence from barbarism, is brought into dispute. More grave, because more fundamental, is the judgment implied in the suggestion that 'progress', like Frankenstein's monster, has outrun the power of man to control it, and that therefore scientific investigation, which by its effect on production and therefore on labour is regarded as chiefly responsible, should be slowed down to enable consumption and employment to make good the lag rapidly forming a vicious circle from which extrication will be difficult or impossible. Although the British Association neither generally nor specifically in the meeting at Blackpool is legitimately to be regarded as the foster parent of pessimism, nor would be prepared to admit the ultimate sanity of any suggested check on scientific research or its application to practical affairs, yet the unanimity shown by the sciences in the recent debates, in diagnosing the underlying causes of the present situation as in some way or other involved in a lack of conscious direction, marks recognition of the gravity of the evil at the same time as it seems to point a way out.

The complaint that the strain of contemporary life is too great for human endurance is probably as old as the association of human beings in anything larger than a family group. Nor is it always the part of the *laudator temporis acti*. It certainly goes back so far as Horace when he longed for the quiet of his Sabine farm; it is familiar in the eighteenth century, as for example in the works of Smollett, and Sir Josiah Stamp quoted an apt example from the "Creevey Papers" in the reference to the "frightful" experience of travelling by rail at the rate of twenty-three miles an hour. These plaints, however, date from before the days of the machine, when individuality still had room for play. The more strenuous nineteenth century, with its doctrine of *laisser-faire*, encouraged the struggle of the individual, while imposing conditions upon labour and production against which it was the sense of the community that the worker should be protected. It is unnecessary to recapitulate the familiar story of the social and industrial development of the nineteenth and early twentieth century; but the principal trends which are germane to the present purpose are the growth of associations of both labour and employers, the application of scientific methods and results to all departments of production, as well as to the well-being of the worker, and the recognition by the community of its responsibility to see fair play as between employer and employed and the consumer and the producer, as well as generally to preserve so far as possible some balance between the rights of the individual and the claims of the group, whether trade organization or public authority.

The application of these principles to a large extent was opportunist, and so far as concerns the application of scientific methods and results to the problems of society and industry, was often more or less a consequence of pressure, frequently considerable, brought to bear on authority from outside. Much has happened since then; and of all the lessons of the Great War, the most enduring and the most far-reaching have been the value of scientific research when applied to the problems and needs of practical life, and the impetus which can be imparted to concerted group effort under direction.

Of these two lessons the latter was already in principle familiar to the anthropologist. It is a form of the struggle for existence whereby man seeks to secure survival through combination in groups which ever increase in size and complexity. As a result of experience in the War, this principle has been transformed into a political dogma. It has produced on pseudo-scientific argument the totalitarian State, whether communist, fascist or quasi-constitutional under a virtual dictator.

The weakness of the totalitarian State is as obvious as its strength. It exalts the whole at the price of individuality, and in so far as it must in self-protection stamp the individuality of the many with the brand of the few, however wise and provident they may be, it will in the long run weaken the whole. For the group to survive must survive through the quality of its individual components. The problem of future research in the biological and humanistic sciences is to solve the equation of group interest and individual well-being. As Sir Josiah Stamp indicated in his presidential address to the British Association, the crisis in world economics and politics has forced it on our attention that there is a vast field in the constitution and character of man, his heredity, his training, his social and economic relations, more especially in relation to changing conditions, which await investigation. However intense and far-reaching may be the efforts of research directed to the improvement of material conditions, the result may be, who can say, perhaps more harm than good unless we understand more clearly than we do at present the whole nature of man and his reactions both as a unit and in the group. In the long run, the race will be to those who solve this problem.

A Text-Book of Unapplied Biology

Why Keep Them Alive?
By Paul de Kruif, in collaboration with Rhea de Kruif. Pp. vii+293. (London: Jonathan Cape, Ltd., 1936.) 10*s.* 6*d.* net.

DR. PAUL DE KRUIF is a writer better known, unfortunately, in his own country than in England. Beginning life as a bacteriologist, he soon abandoned academic science and research, and devoted his talents to the vulgarization (in the French sense) of scientific and medical discoveries—becoming, in his own words, "a sort of human loud-speaker, a barker", telling the world at large about some of the wonders of biology. In "Microbe Hunters" (1926), "Hunger Fighters" (1928), "Men against Death" (1932), he has already related, in colloquial American language, various outstanding 'triumphs' of bacteriology, nutritional physiology, and medicine. All these books are distinguished by the accuracy of their scientific and historical data, though these are often presented in a picturesquely overdrawn manner and from a national point of view not always appealing to a more stolid English audience.

As our author has already employed his scientific knowledge and literary gifts to good purpose, we turn to his latest work in confident expectation that he has again some arresting news to announce. And he has. He has discovered that the scientific and medical marvels which he formerly chronicled so dramatically and so hopefully are not being properly used for the benefit of humanity. Despite all our new knowledge—which he has already been at such pains to broadcast—about microbes, vitamins, and hormones, he finds that American citizens are still dying off like flies from starvation and avoidable afflictions. So he asks with righteous indignation why this is so. If we have not the sense to keep even our innocent little children alive and well in a world of knowledge and plenty—to stop them dying from starvation, and from preventable and curable diseases—why in Heaven's name do we let them live at all?

Both the contents and the temper of this disturbing book can be briefly indicated by the titles of its chapters (I almost said "the texts of its sermons"). (1) Why should they die? (2) Discovery that children are forgotten. (3) Discovery that it's dollars or children. (4) The power of science without money. (5) The people's death-fight. (6) Drouth is a blessing. (7) Who owns our science? (8) Observation of children of the shadows. (9) Should children eat? (10) Children can live! These headings give but a faint idea of the variegated and confusing pattern of the whole: yet the reader who conscientiously follows the author to the last page—undeterred by his seeming inconsequence, verbal exuberance, and eccentric punctuation—will find that the game is worth the candle. He will find that he has incidentally acquired much exact information not only about infant mortality in the United States, the diagnosis and cure of consumption in Detroit, and the horrors of drought in Wisconsin and of the slums in Cincinnati, but also about such apparently irrelevant matters as the discovery of the tannic acid treatment of burns and the birth of the famous Dionne quintuplets in Canada.

From this wealth of detail it is not always easy to disentangle the main argument; but de Kruif appears to be trying to enunciate and solve, for a special case, a general problem of supreme scientific importance. How is it that Man, a supposedly intelligent animal, is still unable to use his painfully earned knowledge properly for the good of his own species? His scientific knowledge is already immense, and adequate for most of his specific needs; yet he has hitherto discovered no way to disseminate it for the benefit of all mankind, nor even to prevent its prostitution for human destruction. (This dilemma is, of course, familiar to readers of NATURE. So recently as July 18, an editorial article noted that "Nothing could be more unscientific than the contemporary armaments race, and the existence of widespread poverty and malnutrition in a period of unparalleled development of the technique of production, and the study of the science of nutrition".) But it makes de Kruif's blood boil when he sees people famishing in one of his United States while 'surplus' food is being destroyed in another: and he is driven almost to frenzy by the sight of children dying of starvation and preventable and curable diseases for lack of the money which his Government could find, if necessary, to kill another nation's children in warfare. He wants to know who is to blame for this sinful situation—and make him suffer for it.

Every man of science must sympathize with de Kruif in his indignation, and must share his passionate desire for reform. Nevertheless, it must be confessed that he himself appears to have found no solution of the fundamental problems which he attempts to formulate; and one may well even doubt whether any solutions are possible by his emotional method of approach. There are passages, it is true, in which he appears to favour some form of communism as a remedy for our present economic, social, and scientific disorders; but he is too great an individualist to pursue that line of argument very far. Moreover, when the question of guilt arises, he has an uncomfortable feeling (haven't we all?) that even he himself may not be entirely blameless—for isn't it *his* duty to do something about it? So he takes refuge in the thought that, after all, he is "only a reporter": it is not his job to put things right. When everything else fails, he seeks eternal truth by fixing his eyes on the horizon of Lake Michigan—just as the monks of Mount Athos formerly did (if we may believe Gibbon) by contemplating their navels.

Such consolations are not for everyone, however, and the question of responsibility for the non-application and misapplication of science has got to be faced more scientifically. In a sense, of course, the blame rests upon all mankind—including men of science themselves: but the excuse that "I am only a reporter" (or "only a man of science", which is equally valid) is surely but an echo of the voice of Cain—"Am I my brother's keeper?" Is it likely to be more acceptable? Yet no man engaged upon research in pure science—a whole-time job—can attend to the proper application of his discoveries (if any) at the same time. Though de Kruif now says in the heat of the moment that "science for science's sake" is "balderdash", he knows full well that science must be made before it can be applied, and that no man can serve two masters.

While reading this just indictment, I have been repeatedly reminded of a more famous work published two centuries ago—"A Modest Proposal for Preventing the Children of Poor People in Ireland from being a Burden to their Parents or Country, and for making them beneficial to the Publick" (Dublin, 1729). In this little tract Jonathan Swift, as everyone knows, answered de Kruif's question. He was equally appalled by the wastage of child-life in his own day, and in this shocking satire endeavoured to stir public opinion by the outrageous advocation of cannibalism. The Dean of St. Patrick's is not noted for the terseness of his style: but in this tract he appears almost a Tacitus in comparison with de Kruif, whose prolixity and varied repetitions and seeming contradictions often obscure rather than stress the points in his argument. His feelings—obviously very noble feelings, inspired by well-authenticated facts—too often overpower his thoughts. Indeed, the very title of his book—commendably short in comparison with the Dean's—typifies this defect. His question is merely rhetorical, and appears to be scientifically unanswerable: at all events, de Kruif is not really concerned with its answer. At the beginning (p. 25), it is true, he postulates that "Children must live"; but clearly this is no satisfactory logical reply to the question why they should be kept alive.

But it is much easier to criticize and compare this challenging diatribe than to answer the numberless questions which it raises. Some of these—though not that asked in the title—are really urgent: they concern all mankind at the present moment. Consequently, I hope that de Kruif's latest utterance will reach the widest possible audience, and will not be dismissed as merely local propaganda: for it is far more than this, and deserves serious consideration by everyone who is not content with modern misuses and non-uses of science and scientific method.

I have referred throughout to Paul de Kruif as "the author" because this book is written in the first person singular, though admittedly the offspring of marital collaboration. (All Paul's earlier books, moreover, were dedicated "To Rhea".) If I now look somewhat askance at their newborn child—still a raw product, whose future development no man can predict—it is surely with no ill-will. Indeed, I sincerely hope that this child may escape the fates of those pitiful other babes about whom its parents write so feelingly, and that it will live to lead a long and useful life in the service of all humanity. CLIFFORD DOBELL.

Atomic Spectra

(1) Introduction to Atomic Spectra

By Prof. H. E. White. (International Series in Physics.) Pp. xii+457. (New York and London: McGraw-Hill Book Co., Inc., 1934.) 30*s*. net.

(2) The Theory of Atomic Spectra

By Prof. E. U. Condon and Dr. G. H. Shortley. Pp. xiv+442. (Cambridge: At the University Press, 1935.) 42*s*. net.

THE experimental study of atomic spectra has a long and distinguished history. Even the descriptive analysis of spectra in terms of series and term values—the systematic botany of spectra—has a history of some sixty years. It is only, however, since Bohr's explanation of the hydrogen spectrum in 1913, and still more since his further work in 1921 explaining the structure of the periodic table of the elements, that any fundamental theory of atomic spectra has been available, or any rapid advance in observation or systematics has been made. Indeed no such advance was previously feasible, even on the experimental side, for the experimenter did not know what to look for. The field of atomic spectra provides in fact a perfect example of the way in which experiment and theory can react fruitfully on each other, yielding advances in our understanding of the field at a rate which could scarcely have been anticipated even by the most optimistic. Since 1921 the advance has been so rapid that it is fair to say, as Condon and Shortley do in their introduction, that the interpretation of atomic spectra is now finished in broad outline. All known features of atomic spectra have been at least semi-quantitatively explained in terms of the nuclear atom, strictly according to the laws of quantum mechanics. The period of fruitful research in atomic spectra is not thereby closed, for there remain many important details to be elucidated further, and the proper relativistic theory of the many-electron system to formulate. None the less an epoch is ended.

The growth of the theory of atomic spectra in its early stages was identical with the growth of the quantum theory. The empirically determined requirements of the hydrogen spectrum, including the Stark and Zeeman effects for that spectrum, with assistance from the spectra of the alkalis and alkaline earths, led by themselves to the formulation of Bohr's correspondence principle. From this principle to quantum mechanics the climb, severe as it proved until led by Heisenberg, is short and inevitable. The study of the tremendous field of more complex spectra played only a comparatively minor role in this development, although the first successful systematizations of these spectra preceded it. Once quantum mechanics had been formulated, it was soon found that the whole body of spectra fell together into one consistent scheme, the unforced immediate interpretation of which remains one of the chief glories of quantum mechanics—an achievement sufficient by itself to convince the most sceptical. It is this complete interpretation which is presented in the two books here under review, in White's from the point of view of the experimenter, in Condon and Shortley's from that of the mathematical physicist.

(1) After an introduction covering the history of investigations on atomic spectra, and the developments made by the old quantum theory, and giving some account of Schrödinger's equation and the Dirac electron, White's book gives a general account of atomic spectra in terms of the vector model. This account is in every way admirable from the point of view of the experimenter, or of the intelligent student who may prefer or be forced to approach the subject with little knowledge of mathematics. All the results of quantum mechanics are stated in the form of rules, for which the vector model provides a reasonable unity of appearance, and are elaborately applied to actual spectra, but the readers of the book are not primarily concerned with the

derivation of these rules from any general theory.

Theirs not to reason why
Theirs but the rules to ply,

and this is certainly a good, possibly the best, attitude in which to begin the study of atomic spectra.

The various rules such as the branching rule, the intensity rules, Lande's g-rules and Γ-rules, the permanence rule for the g- and Γ-sums, can all be presented quite simply and fairly systematically in terms of the vector model, adapted to quantum mechanics by taking the square of any angular momentum vector L to be $L(L+1)$, so long as one is prepared not to worry overmuch about the reason provided by quantum mechanics for the procedure specified by the rule. This is the attitude adopted by White, and it results in a most successful book, which can be heartily recommended to the readers for whom it was written. Some of them may even feel that the presentation could just as well have been even less related to the underlying theory, and that some part of the description of the old quantum theory could perhaps have been omitted.

One of the best features of White's book is the obvious glee with which the author writes of features of the more complex spectra, such as "the great calcium triad". Enthusiasm is infectious, and the reader is conducted willingly through fields which might well have proved arid. His willingness is rendered all the greater by the profusion and excellence of the diagrams and plates. Some of the most beautiful of these are the electron cloud photographs which demonstrate the relationship of the Schrodinger's wave functions to the orbits of Bohr's older theory.

(2) Condon and Shortley have written a book which is as different from White's as two books on atomic spectra could well be. They are concerned almost exclusively with the strict derivation from quantum mechanics of the rules of the vector model and other general features of atomic spectra. The space devoted to comparisons between theory and actual observations has been necessarily reduced to a minimum. Such comparisons can be found elsewhere, notably in White's book.

Many methods of presentation are open to an author setting out to expound the mathematical theory of atomic spectra. The main classes of presentation will be determined by whether one admits or excludes the explicit use of certain branches of pure mathematics, notably group theory and matrix algebra. Condon and Shortley admit matrices and exclude groups. They explain that in their opinion, in which the reviewer concurs, the explicit use of group theory would make too great demands on the mathematical equipment of too large a proportion of those mathematical physicists who might be expected to read such a book on the theory of atomic spectra. Not long ago, the same might have been said about matrices, and even to-day the matrix algebra which dominates large portions of the book may prove a difficulty to some readers, though probably only to the older ones. Even such readers, however, will probably put the book down convinced that matrix algebra has come into the subject to stay, and that to attempt to write the mathematical theory of spectra without this compact and powerful language would be retrograde if not impossible.

It will now perhaps be useful to survey in rather more detail the contents of this book. The introductory matter consists of a résumé of Dirac's exposition of quantum mechanics and his theory of observables, of the matrix algebra of angular momenta and of the classical radiation theory. With this background the argument proceeds to a complete discussion of one-electron spectra, which is then extended to many-electron spectra in great detail. An admirable feature of this part of the discussion (both in Condon and Shortley's and White's books) is that both Russell-Saunders and j-j coupling are considered separately on an equal footing. Both are almost equally important limiting cases, and in Condon and Shortley's book there is an instructive chapter tracing theoretically the transition from one to the other through the various stages of intermediate coupling. Having thus completed the theoretical background used in the systematic description of all ordinary spectra, the authors bring X-ray spectra into the optical scheme in a most satisfactory way by a discussion of the properties of almost closed configurations, of which both X-ray terms and many optical terms in the rare gas spectra are equally examples. The book continues with an excellent account of Hartree's method of the self-consistent field, and of the accurate calculations by the Rayleigh-Ritz method of the normal state of helium-like structures, and another of the interaction between different atomic configurations leading to perturbed series and many-electron jumps. The closing chapters describe the Zeeman, Stark and nuclear effects on atomic lines.

No one but an habitual worker in the field of atomic spectra could hope usefully to criticize in detail an exposition such as the present, and the reviewer can make no such claim. Its power and thoroughness leave the general impression of a work of the first rank, which successfully unifies the existing state of our knowledge, and will prove for many years a starting point for further researches and an inspiration to those who may undertake them.

R. H. F.

Compression Ignition Engines

(1) High Speed Diesel Engines:
with Special Reference to Automobile and Aircraft Types; an Elementary Textbook for Engineers, Students and Operators. By Arthur W. Judge. Second edition, revised and enlarged. Pp. xi + 347 + 41 plates. 15*s.* net.

(2) Maintenance of High Speed Diesel Engines:
a Practical Handbook for Diesel Engine Fleet Owners, Maintenance Engineers, Operators, Drivers and Mechanics. By Arthur W. Judge. Pp. vi + 192 + 32 plates. 10*s.* 6*d.* net.
(London: Chapman and Hall, Ltd., 1935–36.)

(1) THAT a second edition of this book should be called for within two years is a tribute alike to the widespread interest in the subject and to the manner in which Mr. Judge has dealt with it. No doubt most of its readers are interested principally in the application of the compression ignition engine to road vehicles and in a lesser degree to the more difficult field of air transport.

The rate of growth of road usage has been remarkable, as the London streets alone bear witness; but the prospect of there being produced an attractive engine for aircraft operation is still one of 'Jam to-morrow' rather than of anything more immediate. Reliability for road usage has been achieved; but the pursuit of this elusive quality for engines with the lighter scantlings necessary for aircraft has proved arduous. So far, the undoubted merit of freedom from the worse forms of fire risk has been balanced, and rather more than balanced, by the disadvantages of greater weight and less dependability. Indeed, reasonable freedom from forced landings is an essential to any air service which depends on the patronage of the public; whilst for military use the petrol engine gains greatly in any comparison by its lighter weight.

One of the virtues of the compression ignition engine is always held to be the freedom it gives from all the complications attendant on the electric ignition system but, as Mr. Judge's pages bear witness, the alternative complications of fuel pump and fuel piping show that there is little to be gained by this exchange.

In the large-scale use for motor transport, there has been shown to be a large saving in fuel costs, and, in Mr. Judge's view, even the present fuel tax will not cause this to disappear. The general utility of the engine in this field, where high crank-shaft speeds are essential, has been won in no small measure by attention to the production of turbulence in the air close to the fuel inlets. The bearing, on this factor, of ingenuity in cylinder head design is fully brought out by the author.

The book is very practical, and it will find many engineers who will value its possession as a really up-to-date guide on a subject which such a vast number of them have to deal with in their daily work. It is true that it is a compilation of work done by others rather than an exposition by a master, but the latter it does not profess to be.

(2) Mr. Judge's second volume relates solely to care and maintenance, and does not call for special remark. It appears to be a thorough compendium of useful experience and practical hints. It will no doubt find its circle of readers.

Down to Earth:
an Introduction to Geology. By Carey Croneis and William C. Krumbein. Pp. xviii + 501 + 64 plates. (Chicago: University of Chicago Press; London: Cambridge University Press, 1936.) 17*s.* 6*d.* net.

IT is unusual, in Great Britain at all events, to find a book of elementary science enlivened with facetious illustrations. Such, however, is the case in "Down to Earth", a volume of nearly five hundred pages by Croneis and Krumbein, published by the University of Chicago Press. There is a large number of figures of which one may be cited as a sample of many. It is entitled "Earth has not yet answered the question of her origin" and Earth is represented as a girl in a straw hat, short skirt and apron scratching her head, and is being pointed at by three stars in top hats and walking sticks. In addition to the many figures there are sixty-three plates which at first sight look as if they had been taken from some weekly illustrated magazine. Yet the book is a very good one. The plates, each one made up of several good photographs or on occasions diagrams, convey a great deal of sound information on various aspects of geology, palæontology and their applications to modern life. Not all the text figures are humorous; many are the more usual form of diagrammatic illustration, portraits or reproductions of historical medieval text figures. The text is good and conveys a great deal of information. A school boy or girl might perhaps be attracted by the lighter aspects of the volume to absorb the more solid parts, which in fact form the larger part of the work.

Biologie der Tiere Deutschlands

Herausgegeben von Prof. Dr. Paul Schulze. Lief. 37. Teil 26: Orthopteroidea II, Phasmodea, Saltatoria. Von Max Beier. Pp. 233–415. 16.50 gold marks. Lief. 38. Teil 9: Acanthocephala, Kratzer, von Friedrich Bock; Teil 31: Hemiptera III, von Herman Weber. Pp. 9+209–355. 16.50 gold marks. (Berlin: Gebruder Borntraeger, 1934–1935.)

THE first portion contains two chapters, one dealing with the Phasmids (stick insects and their allies) and the second the Saltatoria (locusts, crickets, etc.). While other forms are mentioned in the first chapter, it is largely built round *Carausius morosus*. It includes a good account of the anatomy and histology, particularly of the sense organs, but all dealt with in correlation with function. In addition, the reproductive activities and the reactions of the animal are adequately discussed. The second chapter, which deals with the subject matter in the same manner, actually treats of a number of different species and so has a wider basis.

The second portion deals with two separate groups, the Acanthocephala and certain Hemiptera. The structure and life-histories, including the relationship between parasite and host, are very clearly set forth in some of the better known Acanthocephalids. In the introduction, the classification employed is given, and a few pages farther on is a useful list of fifty-eight worms with their final hosts and, where known, the first and second intermediate hosts also. From this it is clear that in many instances the individual species of parasites show a very wide choice of hosts.

The section on the Hemiptera is subdivided into the Aphids and the Coccids. After a satisfactory review of the morphology of the group illustrated by reference to a series of types, there follows a very useful discussion of the life-cycle of these interesting insects. Much of the information is set forth in the form of diagrams, which facilitate comparisons between the different life-histories. While the part relating to the Coccids is somewhat shorter than that relating to the Aphids, it nevertheless covers the ground adequately.

A good feature of all these contributions is the close correlation between the morphological and functional aspects of the problems. The animals are treated as living units so that the series well merits its title of 'Biology'. All the illustrations are well chosen and well reproduced; the information is up to date and the several chapters are furnished with good bibliographies.

Geometrical Optics

By Dr. H. T. Flint. Pp. ix+266. (London: Methuen and Co., Ltd., 1936.) 7*s*. 6*d*.

DR. FLINT has accomplished a task which leaves teachers of optics very much in his debt. He has produced an elementary treatise which begins at the very beginning of the subject, expounds a rule of signs lucidly and fully, and, after discussing in sufficient detail the topics associated with an intermediate course in optics, goes on to treat of thick lenses, combinations of lenses, aberrations of various kinds, apertures, photometry and optical instruments. Under the last heading are given brief but adequate discussions of the microscope and telescope, the eye and its defects, eyepieces, resolving powers, and various photographic objectives. Those of us who were trained in the optics of a generation ago will recognize the debt that the author owes (and acknowledges) to Drude, whose treatment of the one-to-one correspondence between points in the object- and the image-space is, in general, followed.

That Dr. Flint is the author is sufficient guarantee of the clarity and elegance of the treatment of the subject, and one of the chief virtues of the book is that it leaves the student with nothing to unlearn, whatever may be the direction of his subsequent studies in optics.

Here and there are examples of treatment concerning which divergencies of opinion are permissible. Thus, in discussing focal lines the author very naturally bases his treatment on the properties of lines of curvature—it is the method of approach natural to the mathematician. So far as the average student is concerned, the reviewer finds that method of approach most useful which is based on the properties of the caustic; this, however, is a very minor matter.

If a suggestion may be made, it is that, in a future edition, a few *laboratory* exercises might with advantage be added, and that, in the exposition of the properties of the cardinal points, the Bravais points should not be forgotten.

The book may be unreservedly recommended to students in the final or junior honours grade in the universities.

Physical Chemistry for Colleges:

a Course of Instruction based upon the Fundamental Laws of Chemistry. By Prof. E. B. Millard. (International Chemical Series.) Fourth edition. Pp. ix+524. (New York and London: McGraw-Hill Book Co., Inc., 1936.) 21*s*.

WRITTEN, for the main part, in terms of the classical thermodynamic and statistical theory, the fourth edition of this book, nevertheless, gives adequately the facts of recent discoveries. Chapters involving numerical work are pleasingly free from ambiguity, so that the student should find little difficulty in working through the excellent assortment of problems appended to these chapters, although these exercises would probably be more helpful if the answers were provided.

In his treatment of modern physico-chemical theory, Prof. Millard is sound rather than provocative. Thus, while the existence of activated molecules is deduced as a result of the breakdown of the kinetic theory of reaction, their position in the electro-chemical theory of valency is only briefly mentioned. In the same way, heterogeneous reactions, treated largely as an application of the Phase Rule, might well have been correlated with the modern theories of adsorption and catalytic activation. Minor drawbacks of the book include the lack of formal definition, for example, of heat of reaction, order of reaction, etc., and the ambiguous use of the terms atomic weight, gram-molecular weight, etc.

The Strain of Modern Civilization*

By the Right Hon. Lord Horder, K.C.V.O.

FROM the early days of the primitive curse, life has always imposed its strain upon mankind. It is the penalty we pay for living at all. Philosophers have always assured us that we cannot have life without it. Indeed, they have assured us that some degree of strain is good for us. There is, however, implicit in the title of this discussion the suggestion that the stress of modern life has new elements, and is excessive. In the street, the trained eye detects in the physiognomy of the people the early stages of that concern which, in the consulting room and in the hospital ward, shows itself so frequently as the more established picture of 'anxiety neurosis', unloading itself upon the digestion, the circulation and other bodily functions, which are really more sinned against than sinning. 'Functional' diseases, as against 'organic', have increased, whether in the field of the nervous system proper, the heart and blood vessels or the internal secreting glands. I must not stay to expand, or even to justify, these statements; few, if any, medical men will contest them. In case after case, a tactfully conducted pursuit after fundamental causes removes the screen of headache, insomnia, indigestion and fatigue, and the anxiety factor is revealed.

In the sphere of microbic infections, as I have pointed out elsewhere, we have new diseases for old. Preventive medicine has freed us from many of the severer epidemics, as also from many fulminant sporadic infectious diseases. Tuberculosis has come largely under control. But in place of such plagues as these, there is an increase in the incidence of those more subtle germ diseases which we call "sub-infections", in which the virulence of the microbe is low, whilst the susceptibility of the host is high. In many of these diseases the germ comes from within and not from without: "a man's foes" are "they of his own household". In short, we are becoming the victims of our own saprophytes. And the only reason we can assign for all this is a 'give' on the part of our own resistance to auto-infection—a 'give' which seems to follow a lowering of the control exercised in health by the nervous system. Such control is, in a strict scientific sense, only a postulate; it lacks proof; but is it likely that, with nerve control of so many other functions proved, we shall find that the important function of immunity is an exception?

So much for some of the effects of nerve strain. What of the causes? It is almost platitudinous to speak of the anxiety connected with the competition of living, and now with the equally grave and increasing sense of international insecurity; of the pace at which we live; of the precariousness of life itself in the streets, so that we seem in these days to live by accident rather than to die by it; of the monotony and drabness inherent in many workers' long hours of physical and mental effort; of the lack of air and of exercise and of sleep; of the exciting nature of our amusements, whether the immediate demand for them be normal relaxation or a dope; of noise—needless, stupid, provocative, ill-mannered, selfish noise. . . . Platitudinous, and yet, on reflection, the major premise holds good in respect of all these factors.

There is a notion afoot that, in the last analysis, science is largely responsible for the extent and persistence of much of the strain of modern life. I want to say, at once, that I regard this unloading upon science as mere pusillanimity. I hold the view that it is not too *much* science, but too *little* science, that has helped to get us into this trouble. Or rather should I say, not enough interest *in* science and not enough direction given *to* science. What interest does the average individual really take in science and to what extent is he prepared to encourage it? The answer is, almost nil. Which is odd when we reflect that he recognizes quite fully—as how can he fail to do?—that at the present time both politics and economics—and some would add even religion—regarded as systems existing for human betterment, seem to have failed him, and science alone is not bankrupt. Science has, indeed, loaded man with benefits, but he has shown an indifference to them, or a carelessness and a prodigality in his use of them, which is quite pathetic.

A Spanish writer says in this connexion that, speaking for himself, . . . "the disproportion between the profit which the average man draws from science and the gratitude which he returns—or, rather, does not return to it: this is terrifying. I can only succeed," he continues, "in explaining to myself this absence of adequate recognition by recalling that in Central Africa the negroes also ride in motor cars and dose themselves with aspirin".

Not only ungrateful in thought and attitude, but ungrateful in mishandling the benefits accruing from scientific endeavour. Blame science? We need not drive a car so fast that it kills, or make a loud-speaker so loud that it deafens. Science was made for man, not man for science, and the one thing that matters is control. Are we going to drive the machine, or are we going to let it drive us ? Mr. H. G. Wells, in one of his inimitable word pictures, portrays civilization as a high-powered motor-car gathering momentum on a precipitous hill, a quaking, gibbering monkey at the wheel, impotent to check its increasing speed. Not complimentary, but terribly suggestive.

---

* From the introduction to a discussion in Section I (Physiology) of the British Association at Blackpool on September 15.

Who cares about the direction along which science produces her gifts to mankind ? We have an astronomer royal, but we have no biologist royal, still less a psychologist royal. Is this a survival from the days when we thought the stars controlled our destinies ? But if "the fault . . . is not in our stars but in ourselves, that we are underlings", as I believe it is, should we not 'do something' about this ? Hygiene of the body—the idea seems, at long last, to have been grasped ; 'mental hygiene', after a long and painful labour, is, I think, being born. What of spiritual hygiene, the hygiene of temperament ? I believe that the spirit of man is fundamentally as amenable to scientific investigation, if not to control, as is his body and his mind.

Amongst the remedies for the ill effects of the strain of modern life, I place first more science, and especially science directed towards the study and development of the mind and the spirit of man. Then it behoves us to guard and support all those amenities which are actually in existence or which are struggling for recognition : leisure for the artisan, the factory hand, the labourer, the shopman and shop woman, the housewife—and for "all who grunt and sweat under a weary life" ; slum clearance ; playing fields ; national parks ; the National Trust ; physical training ; adult classes ; pictures ; poetry ; music ; museums ; libraries ; architecture ; quiet for the brain worker and others. Whether our outlook be mainly that of the eugenist or that of the environmentalist, we must not "cease from mental fight" until we have, by these and other means, "built Jerusalem in England's green and pleasant land". I risk platitudes once more but again the major premise holds.

The critic may, however, be saying : "that's all very well ; you are only dealing with the individual ; it is the mass for whom you must prescribe, the mass that is arising here, and there, and that will determine the trend of civilization in the near future, and even determine whether it continues to exist or not". But, personally, I see little hope for the people of Great Britain through mass movements. Fascist or Communist, when individual freedom has been sacrificed, I see no chance of achieving that control in the spiritual sphere through which alone, I believe, salvation can come to the human race. What matters the colour of men's shirts if these are soon to be their shrouds ? Or what matters their numbers ? The falling birth-rate in Great Britain is causing some people concern. As a disciple of Francis Galton I am much more interested in the quality than in the quantity of our people. When the clash comes, if come it must, between these two hordes of the new barbarians—civilized barbarians if you like—it may well be that the salvaging of the world, or its doom, may depend upon whether Northern and Western Europe, and America, have been able to preserve an individualized society, or, like the two opposed masses in the dictator countries, have yielded to the tremendous pressure of what may prove to be a bastard civilization and have caught the infection of despair. If our own individualities refuse to be tub-thumped, or intimidated, into a pulp, all may yet be well and the clash may be averted. Meanwhile, "'a plague on both' their blouses !" We had troubles enough of our own with which we were busily, and not altogether unsuccessfully, coping : the loud-speaker next door, the roar of the sports-model car up the street (night-silence for hooters notwithstanding) ; and now comes another fire-eating speech from a dictator on tour, or an account of one of these orgies of human sacrifice by which an executive hopes to maintain its precarious control. No wonder our nerves are kept on edge.

Much of what I have just been saying may sound like a statement of my own views on international affairs rather than the contribution of a doctor towards the treatment of a disease. But I wanted to emphasize my opinion that remedies that depend upon parading or dragooning patients in the mass are spurious remedies, and are, therefore, unlikely to be finally effective in freeing the world from the strain that it is suffering.

Recently we have been witnessing the invasion of medicine by mass methods, by direct action, by force. The results have been very disappointing. Too often we have had to admit that many of these therapeutic efforts did little more than demonstrate the triumph of technique over reason. We had to start all over again, working out the particular case, and following the indications carefully. That is, we did this if the direct action method still left us a patient to treat. We remembered—what we never should have forgotten—that it is only by this segregation and study of the individual, and attention to his particular needs, that we have any good chance of restoring him to health. It is for this reason that I have dealt with mass movements as efforts towards restoring that sense of security which is essential to national and to international well-being. The analogy from medicine is all against treating the crowd, and all in favour of treating the individual.

It may, however, be advanced that what may not succeed in Great Britain may succeed in Russia or in Germany. Of this it behoves us to hold an open mind. But it also behoves us to be vigilant lest we sell the birthright of our national characteristic, which is individual freedom and poise, for one or other of the vaunted panaceas that are offered us from outside. I say all this at the risk of being charged with egregiousness—a common charge against Britons.

There is another characteristic in a British patient: to treat him successfully he must be treated through his intelligence and through his will, not through his emotions. He responds badly to the '*ça passe*' method.

Nor shall we, if we be wise, listen seriously to the various panaceas offered to us from within. There are several of these. In respect of the worrying menace of war, and the perpetual anxiety it creates, there is the doctor who says: "sign a post-card *against* war, say you won't *have* war". Which sounds reminiscent of that old story, attributed to President Coolidge, who laconically summed up the preacher's sermon on sin by the statement, "he was against it". Or as who should say, "I don't hold with cancer". But who does? This sort of thing doesn't help anybody. Whereas the sentiment implicit in the soldier-poet's question, "Who lives if England dies?" *does* help, nor is the man or woman who is braced by such sentiment necessarily a jingo or a blatant patriot. Ideals are essential for us all, and are invaluable tonics, but the British patient does better on a practical and an attainable ideal than on one which is, in this present world, too visionary. "The test of truth in matters of practice is to be found in the facts of life, for it is in them that the supreme authority resides."

Then, just as we get the hypochondriac in matters of the body and of the mind, so there is in some quarters, or so it seems to me, a tendency to spiritual hypochondriasis. There are folk who, to use Carlyle's significant simile, spend much of their time looking at their own navels, and even comparing them with those of their friends: much too subjective an occupation to be healthy. We break up the hypochondriac situation by exhorting the patient to be more objective in his outlook and to leave his body alone. His body troubles him less when once he effects this orientation. If for 'body' we read 'soul', the same result may be safely predicted from the same treatment. Following a medical thought, I regard these panaceas as being of the nature of quack remedies, because I do not think that they really deal with the facts inherent in the situation. We are asked if Soviet Russia can change human nature. Frankly, I doubt if it can, because I think the change must come from within and not from without. And if we are given time, and given freedom from paralysing fear—fear, the arch-enemy—we can reduce these strains of modern life by effecting a better adjustment in ourselves to the rapidly changing conditions of our times, reducing the pace at which we live, and achieving control. Given time to meet, and to know each other better, we can pool our various national traits. In the last analysis, we are mostly good fellows with similar needs and probably with similar destinies.

When Browning makes Paracelsus say, "Make no more giants, God, but elevate the race at once", he seemed to subscribe to the element of charlatanry with which tradition debits that romantic figure. As I have already said, I do not think the cure will come that way. I believe that only "man can elect the universal man". But I have faith that the human heart *is* "made of penetrable stuff". I do *not* think that "damned custom" has "braz'd it so, That it is proof and bulwark against sense", though at this moment a morbid Hamlet, were he looking on, would doubtless take that view.

I think, rather, that there are still enough people, "whose blood and judgment are so well commingled that they are not a pipe for Fortune's finger To sound what stop she please"—enough of these sturdy folk to check the disease and to re-establish health. The treatment is the treatment of the individual by the individual. Any physician who can inspire "Gentleness, Virtue, Wisdom and Endurance" will help to hasten and establish the cure. Any physician who cannot prescribe these remedies obstructs the cure, and should stand aside.

Is it permissible, in an assembly of scientists, to end on a transcendental note? If so, I would remind myself that the spirit of man, though often needing comfort and reassurance, and perhaps never more than now, is still the dominant factor in all the experiences that it meets, be those experiences in the bodily, mental and spiritual health of the individual or of the race.

"The Lords of life,
I saw them pass,
In their own guise,
Portly and grim—
Surface and dream,
Some to see, some to be guessed,
They marched from East to West:
Little man, least of all
Walked about with puzzled look.
Him by the hand dear Nature took,
Dearest Nature, strong and kind,
Whispered, 'Darling, never mind!
To-morrow they will wear another face,
The founder thou; these are thy race!'"

Evolution of the Solar System

SIR JAMES JEANS opened a discussion on the evolution of the solar system on September 10 at the Blackpool meeting of the British Association. Prof. A. Holmes described the geological evidence concerning the age of the system ; Prof. E. A. Milne discussed its dynamical aspects from the point of view of his recent work on the foundations of dynamics and gravitation ; in the absence of Mr. R. A. Lyttleton, his binary star hypothesis of the origin of the system was described by Prof. W. H. McCrea ; Prof. V. Bjerknes spoke on some hydrodynamical aspects ; Dr. Harold Jeffreys stated some problems raised by the chemical composition of the planets, and summed up the discussion. Some of the points raised are summarized here.

No theory of the origin of the solar system has yet gained general acceptance. Indeed, until quite recently, none existed which satisfied all the following simple general tests : it should explain (i) the production of satellite systems as well as the planetary system ; (ii) the regularities in the sequence of the planetary masses, of the ratios of the masses to those of the largest corresponding satellites, and of the numbers of corresponding satellites, when the planets are arranged in order of distance from the sun ; (iii) the birth of the system at an epoch when the physical constitution of the sun was not greatly different from what it is at present ; (iv) the large amount of angular momentum possessed by the outer planets.

Arranging the chief theories in order of the number of bodies involved in the birth of the system, we have first Laplace's nebular hypothesis. The origin is sought in the cooling, and consequent shrinkage and speeding up of the rotation, of a single nebular mass of gas extending initially beyond the orbit of the outermost planet. The planets are supposed to be formed from rings of matter thrown off in the process of shrinkage ; but there is a failure to explain how such rings could condense into planetary form, or how they could possess the observed amount of angular momentum even were the condensation achieved.

Laplace's theory is found, in fact, to involve an insufficient number of adjustable parameters. So various subsequent theories (Buffon, Proctor, Bickerton, Chamberlain and Moulton, Jeans, Jeffreys) have appealed to the intervention of a second body. Some twenty years ago, Jeans proposed his tidal theory, which at the time was the most successful in this category. A second star was supposed to have described a hyperbolic orbit about the sun and it was shown that, if the approach had been sufficiently close, the tides raised in each body by the gravitational pull of the other would have become unstable and grown into a great filament of gas in the space between the two. The gravitational instability of this gas would cause it to condense into planetary masses, some of which would be retained in the gravitational field of each of the two stars. This theory is particularly successful in explaining the regularities noted under (ii), but, as Jeffreys and H. N. Russell have pointed out, and as its author admits, it again encounters difficulties with regard to the peculiar distribution of angular momentum. Some of the difficulties Jeffreys has tried to remove by imagining a still closer encounter of the two stars than Jeans had postulated.

Russell was the first tentatively to suggest that three bodies had been concerned in the production of the solar system, by supposing that the sun was originally a double star, and that the planets were formed by an intruding star encountering, not the sun itself, but its original companion. The actual production of planets by the encounter would be supposed to proceed as on Jeans's theory, but it would now clearly be possible to account for their large angular momentum about the sun, or, what comes to the same thing, their large distance from the sun. Russell himself saw difficulties in explaining how the companion and intruder could both escape from the sun after the encounter, and still leave the planets entangled in the sun's field. R. A. Lyttleton, however, independently put forward the same hypothesis, and at the same time showed that these difficulties are not inherent in it. He has demonstrated that, for ranges of real values of the initial velocities of the bodies involved, it is possible for the encounter of the companion and the intruder to communicate velocities to them which carry them both "to infinity" in different directions, while parts of the tidal filament formed between them, and endowed with velocities intermediate between those of the escaping stars, would have velocities insufficient to get away from the sun's gravitational field. Further, this may happen for initial velocities of the intruder relative to the sun of the same order of magnitude as the observed relative velocities of stars in the same neighbourhood of the heavens.

The theory can be developed to account for the similar sense of revolution of the planets round the sun, for their rotations, and for the existence of satellites. The latter are supposed to be formed by tidal encounters of pairs of planets when, in their revolution round the sun, they both arrive back simultaneously in the same neighbourhood as where they were originally formed. That they should do so before they have had time to condense appears improbable, and this is one of the objections that have been raised against the theory. Nevertheless, so far as Lyttleton's theory has been worked out—it is still in its early stages—it does seem capable of accounting for all the *dynamical* features of the solar system.

Geology cannot say anything about the origin of the earth, but from radioactivity data it can set a well-established lower bound to its age. The generally accepted theory of the formation of rocks has indicated where the oldest exposed examples are to be found, and the lead-ratio method has shown these to be about 2,000 million years old, but their constitution shows them to have been made, by weathering and fusion, out of still older rocks. However, combining this information with that got by Paneth concerning the age of meteorites as given by their helium content, we are led to the figure of about 2,700 million years as the age of the solar system. Geological evidence based on seasonal effects preserved in the structure of the varved clays, and on the recurrence of glaciations, shows further that there have been no large changes in the dynamical and thermodynamical relations between the earth and the sun for something like 2,000 million years.

A study of the chemical composition of the planets leads to many grave difficulties, as Jeffreys has emphasized. For example, in the case of the outer planets, the order of increasing mass is the order of decreasing density, which seemingly admits the explanation that when the masses were gaseous the stronger gravitational fields were better able to prevent the lighter elements from diffusing away into space. But now for the inner planets, Mercury, Venus, Earth, Mars, and also the moon, the order of increasing mass is the order of *increasing* density, which is inconsistent with any such simple explanation. Again, the earth consists of a rocky shell of mean density about 3·3 and a central liquid (probably iron) core of mean density about 12. The mean density of the whole moon, on the other hand, is about 3·3, so that it evidently does not possess a heavy core. This suggests that, if the moon was formed by the breaking up of a planetary mass, then it took place after the heavy elements in the latter had had time to settle down towards the centre, indicating that the formation of the satellite took a considerable time. However, most theories of the formation of satellites require them to have been formed very early in the history of the planets. Also it is difficult to explain how the earth retained any light elements unless its crust solidified very quickly, and it is then difficult to see how the moon could have been formed after solidification. In fact, in the present state of the theory, any explanation of one feature of the chemical composition of the solar system appears to be contradicted by some other feature.

The difficulty about the angular momentum of the system has been mentioned. Lyttleton's theory is the most successful attempt hitherto made to resolve it on the basis of ordinary mechanics. There may still be other ways; for example, E. W. Brown has pointed out that the theory of the perturbation of one planet by another might lead to an exchange of angular momentum between them, if it were carried to a higher degree of approximation than is usually done. But a much more fundamental resolution of the difficulty is now put forward by E. A. Milne on the basis of his recent work on the foundations of dynamics. In this work he starts from observers' immediate consciousness of *time*, and their description of motion based thereon, and is able to derive the forms of the laws of dynamics and gravitation from purely kinematical considerations. He postulates the equivalence of observers in regard to their observation of each other and of the rest of the universe, but he does not need to appeal to experience for any empirical 'laws of motion' or of 'gravitation'. His results are derived first in terms of *kinematical time* t. He then finds that they pass over into the local empirical Newtonian forms on transforming to *dynamical time* τ, where $\tau = t_0 \log (t/t_0) + t_0$, and t_0 is the present value of t obtained from the expansion of the universe. The value of t_0 is about 2×10^9 years, which is also about the age of the solar system given by radioactivity data.

So this would place the origin of the solar system at about the singular epoch $t = 0$ occurring in the kinematical theory. If the correspondence were exact, then, since $\tau \rightarrow -\infty$ when $t \rightarrow 0$, the age of the system, reckoned by dynamical events such as the revolution of a planet round the sun, would be infinite. In other words, in dynamical time the solar system never had a beginning. This suggests a reconciliation between the 'short' and 'long' time scales, which have presented inconsistencies in connexion with many cosmological problems.

Another consequence of the theory is that angular momentum is not a time invariant, but the angular momentum of any local system grows at a rate proportional to itself. Thus small initial differences of angular momentum tend to be magnified as time goes on. This would remove difficulties connected with the rotation, not only of the solar system, but also of spiral nebulæ, in which the amount and distribution of angular momentum has long been a puzzle. It should be added, however, that this theory also has yet been given only in a preliminary form. W. H. McC.

Palæontology and Humanity*

By Prof. H. L. Hawkins

PALÆONTOLOGY gives no direct evidence as to the origin of groups, of whatever taxonomic grade; its scope is limited to records of the later stages in the careers of groups already in existence. This is not to deny that the presumptive evidence for the birth of new types is overwhelmingly strong; but actual tangible proof of their parentage and generation is lacking. A palæontologist is more of an undertaker than a midwife.

Again, fossil evidence cannot give convincing demonstration of the origin of structures in organisms; its scope is restricted to observation of the fate of those structures after they have appeared. There must always be a theoretical quality in attempted explanations of the development of new characters; there are facts recording what happens to them in course of time.

The only language which adequately expresses the nature of morphogeny is that used in description of individual life. Structures, once originated, pass through stages of development, modification and amplification that are closely analogous to the phases of personal history, both physical and psychological. There is a continuous duplicity, in that intrinsic characters are involved with external requirements; environment is educative but not creative. There is a limit to the response to environment possible for any structure; if that limit is exceeded, disaster results. Every character of an organism, like every complete creature, is more responsive to environmental influence in its early history than later. Directions of development induced or encouraged by environment become gradually ingrained; just as practices oft repeated become ineradicable habits. In contrast with modern municipal tendencies, trolley-buses are transmuted to trams.

The several characters of an organism are at once independent and inseparable; each can follow its own line of development, but unless a balance is kept within the whole series, collapse is certain. Just as different groups of organisms show very different evolutionary speeds, so the various structures in a single organism become modified at varying rates. The attainment of mature perfection from a stage of immaturity can never be more than a transient phase on the way to a fresh disproportion comparable with senility.

Structures, and with them the organisms to which they belong, grow old, exhausted or hypertrophied by their own intrinsic expenditure of evolutional 'effort' amid an ever-fluctuating embarrassment of circumstance.

We come to the conclusion that the oracular recommendation to know ourselves is a guide to the secret of evolution. Physically and (in the human case) psychologically, we live our lives as compromises between hereditary tendencies and environmental requirements. As we grow older our accumulated load of compromise becomes an obsession, reducing our capacity for further efforts of the kind; and our environment never tires in its changefulness.

If we consider these principles in the light of the struggle for existence, we find that those types which can attain the most perfect harmony with their environment will flourish proportionately. But their success brings Nemesis in its train; for speedy evolution towards dominance implies continuous speed; the perfection point is passed by the same momentum that reached it. Undoubtedly the victor in the struggle for existence wins the prize; but the prize is death.

When we attempt to apply to human affairs the principles of evolution as shown in palæontology, many difficulties appear. Not the least of these is the impossibility of a dispassionate outlook; we are proverbially unable to see ourselves as others see us. Another serious difficulty arises from the shortness of the time during which our species has existed, and the paucity of trustworthy evidence that it has left of its history.

At the outset we must admit that the basis of our analysis of mankind will be on a different plane from that which we employ in the case of other organisms. Morphological and physiological characters change so slowly that we cannot expect to find much alteration during our brief career; and in any event there is practically no evidence of that sort available. But if the conclusions already reached as to the universality of the law of evolution are accepted, it matters not a whit which particular attribute of an organism we select for study. Behaviour is but an expression of the reaction between the qualities of an organism and its environment, and civilization is a kind of behaviour. This argument is not so specious as it may appear, for the evidence available to check its validity is ample.

---

* From the presidential address to Section C (Geology) of the British Association, delivered at Blackpool on September 14.

Before following that line further, it will be well to attempt an estimate of the qualities of the human species as they appear to a palæontologist. This is a dangerous task ; for I am bound to omit, for the time being, reference to many human attributes. I must appeal for patience ; I am fully aware of the incompleteness of the analysis I am about to make ; later, in a desperate attempt to arrive at a happy ending, I propose to give consideration to those qualities in man that truly differentiate him from other animals.

If it be asked how a student of 'lower' orders of organisms (and those defunct) can presume to include the human race in his purview, a plea of justification can be made on two grounds. Mr. Tony Weller gave it as his opinion that "the man as can form a ackerate judgment of a animal can form a ackerate judgment of anything". This generalization, like all others, may be debatable ; but the course of human history, in so far as it is known, shows features typical of the course of evolution revealed by palæontology.

The outstanding physical peculiarity of the human species is its upright posture, a feature to which many of its bodily structures are far from completely adapted. In spite of its relatively large size, the human body cannot be claimed as exceptionally capable. A man stripped of the instruments of his devising, left to compete on equal terms with the other occupants of his restricted environment, would stand no better chance than they. It is true that he could perform most of the actions expected of land animals, but none of them superlatively well. Were he compelled to rely on his bodily characters alone, there would be little more reason to single him out for special consideration than there would be the capacity to do so.

The mental powers of man are those that place him in a category apart from other creatures. By the exercise of his wits he can find compensation for structural shortcomings, and challenge, defeat and control all other living things. With the help of the machines that he invents, he can project himself successfully beyond the normal range of terrestrial animals, transporting his body and his habits over the sea and through the air. He can, within fairly wide limits, overcome the influence of environment.

With no intent to belittle the mechanical achievements that have brought man to his commanding position, we must admit that few of them can be claimed as original. They are copies, often improved editions, of devices that already existed in the animal creation, coupled with applications of natural forces that are as old as the world. Man's capacity for generalization has enabled him to foresee the effects of his inventions, and so to reduce the time that would otherwise have been spent on the costly method of trial and error. He can transmit his experiences to his own and following generations, so preventing (for those who listen) a wasteful repetition of mistakes. The speed with which he has beaten all other creatures at their several games is commensurate with the degree of his success. Paradoxically he has become supremely generalized by the exercise of a highly specialized faculty.

It is difficult to find any type of animal behaviour in which man cannot excel. Whether in the strictly mechanical processes, such as locomotion or building, or in the more subtle qualities of affection and aspiration, he stands revealed as an exaggerated animal. There are no activities, constructive or destructive, and no habits, pleasing or loathsome, in which he cannot outdo the most accomplished animal.

This analysis leads to a somewhat equivocal result. On one hand, the high cerebral specialization that makes possible all these developments, and the extraordinary rate at which success has been attained, both point to the conclusion that this is a species destined to a spectacular rise and an equally spectacular fall, more complete and rapid than the world has yet seen. On the other hand, the wide range of directions into which the specialization extends, and the measure of control over environment that it entails, seem to suggest a peculiar kind of plasticity that might pass for generalization, with the consequent hope of a long time-range. In this uncertainty we must look for such facts as are available, facts of history which are at least comparable with the record of palæontology. But first we must estimate the relative value of the evidence afforded by human history.

Fossils and historical documents alike give but a fraction of an account of the matters of which they treat. In both cases the story of the early stages of racial progress is imperfect and often mythological ; the episodes of decline and fall are more fully documented. But, in contrast to palæontological evidence, human accounts are always suspect. Written records of events represent an impression made on one, or at best a few, minds ; they may—indeed they must—be tainted with prejudice and ignorance even when they are not deliberately falsified. The impious rebellion of one writer is the glorious revolution of another. Whatever may be the criticisms levelled at the transcribers of natural history, no doubts can be cast on the essential truth of the record they try to interpret. As an academic proposition, it may be debated as to whether a misread fact is preferable to a misread falsehood ; but there is at least a chance of finding the truth in the former case.

Again, the bulk of human history is the record of the performance of a few actors on a specially selected stage; palæontology, with all its imperfections, gives a picture of events in fairer proportion. The parts of human history usually recorded represent the activities of man the intensified animal, rather than of man the half-fledged angel. The behaviour of the animal is the more rational, and so easier to remember and describe. But from very early times another factor has entered into human affairs—a factor illogical and wayward, but every bit as real to a man as his animal qualities. This factor, which we may call 'altruistic', makes human actions often unintelligible in the present, and still more so in the past. For example, it is easier to find a rational explanation of the presence and characters of a *Micraster* in the Chalk than to form a plausible hypothesis as to the meaning of the Stonehenge that men erected over it. Man can safely claim to be unique, for he is the only irrational creature in the world. A palæontologist may be excused for looking askance at a record of creatures like that written by one of themselves.

Nevertheless, man leaves other traces of his activities besides written screeds, and many of these records are as revealing, and as unintentional, as the shell of a mollusc. By piecing together archæological materials, and fitting documentary accounts into the plan of this mosaic, a conception of human history can be gained that comes within measurable distance of scientific evidence. We have more established knowledge of the Belemnites than of the Incas, but perhaps we know almost as much about the Romans as about the Trilobites.

It would be wearisome to reiterate the various features wherein the history of human affairs corresponds with the course of evolution in other groups. Whether we consider individual lives, dynasties or empires, the same depressing story applies. Some races, once dominant in their particular sphere, have disappeared entirely; others, fallen from high estate, linger in inglorious decay. But all those brave civilizations and empires of which we have records seem to have shown a succession of similar histories. They have risen from obscurity through possession of successful attributes, and have reached the peak of their power only to pass it. Some have rotted away quietly, others have fallen before the onset of less rotten stocks or perhaps of extra-human disaster. Many of the early empires were on so small a scale that their rise and fall had merely local effect; others have been more comprehensive, and their dissolution has spread havoc over wide areas of the world.

Until comparatively recently, there has been a persistent proportion of 'backward' types, unaffected by the civilizing influence of the progressive powers. These have remained as a quiet background to the transient pyrotechnics of the others. They remained to provide a new upstart when the current one had crashed. To-day there are few races of this kind left; almost all mankind has encountered civilization and either perished or been transmuted. The fatal complexity of civilization grips the whole species, crushing it into unity.

The specific causes of the collapse of once dominant races are doubtless varied; but there is general agreement that one universal factor in disintegration is complexity, an aspect of over-specialization. The units of an empire, be they individuals or factions, tend to work together in harmony during the period of upward struggle; but when a position of dominance is won, they continue to struggle. When there are no new worlds to conquer, they begin to fight among themselves. Selfish aims replace patriotic ones, and the community becomes discordant.

The correspondence between this state of affairs and the morphogenetic trends in other races of animals is so close that it needs no elaboration. Those who deny that human institutions are subject to the laws of organic evolution know either no history or no palæontology. Many proverbs give epigrammatic statements of the principles of evolution in imaginative terms.

"Ill fares the land, to hastening ills a prey,
Where wealth accumulates and men decay."

The history of extinct empires, which should be studied as a cautionary tale, is commonly regarded as providing an example to be followed. Human nature has the curious trait of gambling against the laws of cause and effect. We always hope that the fate that befel our predecessors will pass us by. Babylon, Egypt, Rome, Spain all traversed the same track; and to-day we follow in their footsteps hoping to reach some different goal.

If this were all, man's outlook would indeed be dark. According to temperament we might as well sit with folded hands in a darkened room awaiting the inevitable end, or meet the crash with ribaldry and riot. Our peculiar quality of superior mentality seems but a suicidal acquisition, hastening and intensifying the imminent doom. But the human mind is more than a fabricator of evanescent institutions. It can transcend utilitarianism (wherein it but exaggerates animal qualities) and can form idealistic conceptions.

Ideas of chivalry, honour and self-sacrifice have no place in the struggle for existence; but they are inherent in all but hypersophisticated minds. Among ordinary folk, conceptions such as these are stronger incentives to action than animal impulses, as even the most rascally demagogue knows. Learning, philosophy and art are realities to which men will devote their lives, creating rather than copying, with no ulterior or mercenary aim. The arts and virtues bring a new and incalculable feature into the story of evolution. Some, at least, of their achievements outlive kingdoms and empires, seeming immortal.

Men are, for the most part, enthusiastic admirers of virtue, even to the extent of devising laws to ensure its maintenance. Very many of them are actual exponents of virtue in their personal relations; but in public affairs and in the mass they are often content to behave as animals rather than as men. "Manners makyth man" is perhaps the most concise specific diagnosis ever published. But there is only one law of evolution, common to individuals and races alike. If mankind as a whole neglects its "manners", it abandons any claim it may have to qualitative difference from other animals. There is no doubt of man's ability to become the most successful type of animal that has ever existed; but the reward of success in that direction is death.

The love of truth, greatest of all virtues, is especially an attribute of men of science. In this we are idealists, for the truth is unattainable, however worth the seeking. We know that all the progress that our species has made, in material as well as in mental affairs, is the result of the search for truth. We find ourselves strangers in a world riddled with more or less blatant deceit; but we still follow our ideal, confident that all other paths are blind. We recognize in the conception of truth something eternal, not subject to the laws of change and decay.

We know that idealism is the goal and incentive in all actions that can truly be described as human. To the idealist, environment is something to be overcome or adapted into service; the story of human progress is one of triumph over circumstances. The self-styled 'realist', who advocates acceptance of, and submission to, his temporary environment, is less than a man; he follows in the tradition of the beasts that perish.

To idealists palæontology has no message, save to welcome them as something new in Nature. To realists, who seek material success in the struggle for existence, palæontology, with millions of years of history as its authority, declares emphatically, "You have been warned."

Obituary

Mr. C. Fitzhugh Talman

WITH the death on July 24, at the age of sixty-one years, of Mr. C. F. Talman, the U.S. Weather Bureau loses one of its best known members.

Talman was born at Detroit on August 31, 1874, and joined the Weather Bureau in October 1896. From 1898 until 1899 he was in charge of the meteorological stations maintained by the United States in South America and the West Indies; afterwards he was attached to the Weather Bureau Library, where he found his true vocation. He received the official title of librarian in 1908, and though he became junior professor in 1912, professor in 1914 and meteorologist in 1922, he remained in charge of the library throughout. He was intensely interested in bibliographical work, and his knowledge of meteorological literature became almost unique. In addition to the annotated lists of new books and papers which he compiled regularly for the *Monthly Weather Review*, he delved deeply into the history of meteorological terminology, publishing his results in semi-popular articles on "The Language of Meteorology", "The Meteorological Isograms" and "The Vocabulary of Weather". The last, which was reprinted in the *Quarterly Journal of the Royal Meteorological Society* for 1925, ends with the words: "I have been gathering wind-names from the literature of all countries, ancient and modern, for many years, and endeavouring to elucidate them from both the etymological and scientific standpoints. . . . It is a fascinating occupation and I only regret that I have, apparently, the whole field to myself".

Another outcome of Talman's hobby was his selection as meteorological adviser for the "Standard Dictionary" in 1910–11. He had a pleasant literary style, which also found expression in two popular books "Meteorology, the Science of the Atmosphere" (reprinted in 1925 as "Our Weather") and "The Realm of the Air" (1931) and in numerous newspaper articles, but his interest was the collector's rather than the author's, and he published only a small part of his material. It is greatly to be hoped that means will be found for editing and publishing his notes.

WE regret to announce the following deaths:

Dr. J. B. E. A. Charcot, the well-known French explorer of the Antarctic, on September 16, aged sixty-nine years.

Mr. J. W. Gordon, K.C., honorary secretary of the Optical Convention in 1912, and author of "Generalized Linear Perspective, with Special Reference to Photographic Land Surveying", on September 21, aged eighty-two years.

Mr. Ernest Payne, a pioneer in X-ray research work, on September 20, aged seventy-six years.

News and Views

Problems of Present-day Astronomy

In connexion with the recent meetings of the British Association, Sir James Jeans delivered a public lecture at Southport on Friday, September 11, on "Some Problems of Present-day Astronomy". He confined his attention to theoretical astronomy, and dealt almost exclusively with large-scale problems concerned with the character of the universe. After a brief survey of the general structure of the stellar universe, Sir James described the various kinds of nebulæ, directing attention in passing to Kuiper's recent discovery, in a planetary nebula, of "what may well prove to be the smallest of all known stars"—a body with a radius about half that of the earth, a surface temperature of about 2,800° C., and an average density about 36 million times that of water. The theory that the extra-galactic nebulæ were formed by condensation out of an originally unstable continuous mass of gas filling all space next claimed attention, and Sir James remarked that mathematical investigation shows that condensations in such a medium would be "on something like the scale of the observed nebulæ, and would be at something like the same distance apart".

Sir James then turned to problems concerning the character of space. Relativity taught us that the total volume of space was finite—a statement apparently at variance with a later suggestion that the curvature of space might be negative and with Einstein and de Sitter's demonstration that it might be zero—but the latest observations disclosed no thinning out of distant nebulæ to indicate that we have yet explored an appreciable fraction of its extent. The systematic separation of the nebulæ from one another was described from two points of view—first as a movement of bodies in a structureless space and secondly as a system of drifting 'straws' revealing the motion of 'currents' in a space whose character the motions served to indicate. For knowledge of the original and present size of space we are dependent on theoretical arguments, and Sir James gave in this connexion a brief description of the theory of Sir Arthur Eddington relating the expansion of the universe with the mass of the electron. According to this theory, the radius of the universe was originally about four times the distance of the farthest nebulæ now known, and has since expanded about tenfold. This consideration would seem to call for further elucidation of the earlier remark that the theoretical separation of the condensations in the primeval universe is about the same as that of the observed nebulæ. The lecture was liberally illustrated by lantern slides.

Preservation of English Scenery

Several important aspects of the preservation of English scenery were mentioned by Dr. Vaughan Cornish in an address to Section E of the British Association at Blackpool on September 14. In the first place, insisting that a scene from which Nature has been expelled is no fit dwelling place for man, he urged the brightening of towns by rebuilding schemes which give higher buildings, and that in a smaller area accommodate the same number of people, and so leave land free for gardens and boulevards. Dr. Cornish went on to insist that the mere preservation of monuments of antiquity is not enough. It is necessary to preserve a contemporary background as in the case of Stonehenge, the Roman Wall, and the ancient earthworks of the Downs. In these respects, however, the danger to natural amenities is less great than in the threat to the cliff-lands of England and Wales. A considerable extent of our five hundred miles of cliff-land is in danger from bungalows, hotels and other buildings. Before it is too late, the last of these cliffs should be acquired and preserved as national parks. This would necessitate the acquisition of a strip little more than 100 yards in width. Several stretches of Cornish cliff-land are specially suited for national reservations, but it will have to be accomplished soon or the builder will have damaged them beyond redemption. The concluding part of Dr. Cornish's address was devoted to a plea for the recognition as national parks of the New Forest, the Forest of Dean, the Pennine Moors and the Lake District. Cliff-lands, woodlands and mountains would then be represented, these being the three types of English scenery of special importance.

Angiolo Filippi (1836-1905)

October 23 marked the centenary of the birth of a leading Italian medical jurist, Angiolo Filippi, the son of a distinguished medical practitioner of Florence. He studied medicine at Pisa, and directly after qualifying gained some useful knowledge for his subsequent career first as a prison doctor and afterwards in the campaign with Garibaldi, where he acquired considerable experience of gunshot wounds. In 1865 he distinguished himself by his devotion to the sufferers from the cholera epidemic at Ancona, San Severo and Apricene. In 1875 he became assistant to Prof. Bellini, who occupied the chair of legal medicine at Florence, and succeeded him in 1884. His "Manual of Forensic Medicine", of which the first edition appeared in 1889 and the fifth in 1919, was the first of its kind to be published by an Italian expert, and proved an indispensable work of reference to the medical and legal profession in Italy. His other works were "A Manual of Thanatology and Traumatology" (1877) and "Medico-legal Exegesis of the Method of Giving Evidence" (1882). He founded a laboratory for medico-legal research in Florence, and his methods of investigation were followed in other Italian schools of medical jurisprudence. He died on December 30, 1905.

British Commonwealth Scientific Conference

A CONFERENCE was opened by the Right Hon. Walter Elliot, M.P., Minister for Agriculture, and attended by representatives of the Governments of all portions of the British Commonwealth, on the morning of Monday, September 21, in London. Its chief function is to examine the work and future of a number of scientific organizations established on a co-operative basis to perform a common service in various branches of agricultural scientific research. As a result of the Imperial Agricultural Research Conference of 1927, the several Governments of the Empire agreed to establish bureaux or centres of information in eight branches of agricultural science, financed by contributions from all parts and controlled by a council representative of all parts of the Empire. To these, the supervision of two older institutes was added in 1933 on the recommendation of the Imperial Committee on Imperial Economic Consultation and Co-operation. In addition, the Conference is considering the future of certain research schemes to which several parts of the Empire now contribute, and also further methods of the interchange of information and closer collaboration in scientific work.

AFTER the opening meeting on Monday, the Conference inspected the bureaux and centres of information which deal with mycology, soil science, animal health, animal nutrition and genetics, plant genetics (non-herbage and herbage), fruit production, and agricultural parasitology. The Conference re-assembles in London on October 2. The Executive Council of the Imperial Agricultural Bureaux, of which Sir Charles Howell Thomas is the chairman, is responsible to all Governments of the Empire equally for the administration of these common services, and in conformity with the resolution of the Imperial Conference of 1926 is constituted on a basis of equality of representation. It was decided by the Governments in 1933 that where such common organizations are formed, their activities should be subject to detailed examination at periodical conferences. This Conference serves that purpose.

Species in Foraminifera

THE veteran palæontologist, Frederick Chapman, who has retired from the National Museum at Melbourne and is now consulting palæontologist to the Commonwealth of Australia, has contributed to the *Melbourne Age* (under the initials F.C. and under date February 8, 1936) a column headed "The Species Nightmare: an Absorbing Scientific Problem". One of the oldest living authorities on the Foraminifera, trained under H. B. Brady, W. Kitchen Parker and W. Rupert Jones, whose assistant he was until his appointment to Melbourne, he deals with this difficult question, quoting Mr. Heron-Allen's communications to NATURE of July 14, 1934 and November 16, 1935. Frederick Chapman deals with it in connexion with other branches of palæontology, and deplores what Heron-Allen termed "the commercialisation of Protozoology", and his article, which is worth the serious attention of all systematists, but is too long to quote adequately, should receive careful attention. Mr. Heron-Allen is consulted by many of the rising school of petroleum geologists at the Natural History Museum, and, regard being had to the deplorable fact that their lists of species are now regarded as a 'trade secret' not to be divulged for the information of rival petroleum merchants, his advice to these young men is to adhere to the genera established by the great nineteenth century school, both in England and on the Continent of Europe, and to distinguish their species, for their own reference and guidance, only by numbers, or by letters of the alphabet, ignoring the thousands of names given to minor varieties by the American School. By this means they can save themselves an immense amount of labour and brain-fag, and their tabulated results are quite as useful as they would be if they were overloaded by a vast nomenclature which it is impossible —and unnecessary—for the human brain to retain.

Invention and the Modern State

THE externals of modern civilization are the products of invention, and a scientific analysis of invention, what it is, what causes it and whither it is leading us, is long overdue in England. In such an analysis the statistical method must predominate and the easy generalization will have no place. It may require research of a difficult and unusual kind, but unless we know, for example, accurately and in detail, the origins, the training and the methods of successful present-day inventors, we do not know the sources of the real progress-making inventions of to-day, and while we are ignorant of that vital fact the recital of a short list of so-called working-man inventors of the eighteenth century is not merely valueless but also misleading. Mr. C. W. Marshall has just concluded in the *Inventor* a series of articles on "The Science of Invention". In them he attempts to interest and guide inventors of various degrees of proficiency, but, although the trend of recent patent applications can be learned from them, the articles are entirely devoid of statistics. As a consequence of this and of the very diverse standards of the inventors to whom the articles are addressed, their total effect is confusion. At one place advice is being given as to the "psychological factor"; for example, "a camera idea, may be submitted to manufacturers in the autumn so as to be ready for the spring sales". Shortly after this we learn—or do we ?—that the "price of inventions used to vary from £1,000 for 'gadgets' to half a million for inventions such as refrigeration and automatic photo machines". Again, "There is a ready market for inventions which cheapen production of exclusive products. By introducing mass-production machines and an entirely re-designed, simplified product the early Fords were able to tap the potentially great motor-buying public".

No one, it would appear, would care to challenge Mr. Marshall's contention that "so keen is the competition, so deep the technical advance now, that the principle of hit or miss, except perhaps in the gadget class of invention, is not applicable, and the complete inventor is a development of the scientific researcher". But to such a man, the suggestion that he would find it worth while studying Max Planck, Einstein and Eddington would come rather late, while that suggestion, even if accepted, would have no utility to the 'gadget' producer. The high hopes raised by the receipt of a treatise with the title "The Science of Invention" remain unfulfilled by Mr. Marshall's series. An authoritative examination of the position of invention in the modern State is still needed. In such an examination the commercial aspect may well prove to be insignificant, although research by one man or one set of workers may have to be restricted to the material inventions, leaving such things as modern systems of government, the most striking development of man's inventive faculty, to the historian or the alienist. From a calm investigation of the uses of material advances it may be found that they follow social changes and are called forth by them: but research is necessary to discover the vital facts of modern invention and, in Great Britain at any rate, there is little evidence that such research is being carried out. Is it fantastic to believe that if it is ever adequately made, we shall have general consent to the idea of complete control by the State of the inventive faculties of its members ?

Viability of Plant Structures

THE question of the length of the period of viability in seeds and other plant organisms is constantly cropping up, and, although a great deal has been written about it, there is still much to be discovered with regard to the actual length of time seeds and spores can remain viable. Reference was made to this problem in NATURE of May 2, 1931, p. 675, and an article on the subject was published in the *Kew Bulletin* of 1933, p. 257. In that article, all the cases of longevity that have been definitely authenticated were brought together. Possibly the oldest case is that of *Nelumbo* (the Japanese lotus) recorded by Ohga in the *Botanical Magazine* of Tokyo, 1923. Seeds of *Nelumbo nucifera* were found in a peat bed buried under 2 ft. of loess in Southern Manchuria. The seeds all germinated and it is estimated that they were at least 120 years old and may have been as much as 400 years. It is well known, of course, that poppy seeds and charlock can retain their viability for very long periods, but for how long one cannot say definitely. According to an announcement in *The Times* of August 19, M. P. N. Kaptereff has succeeded in reviving plant organisms which have lain in the earth for thousands of years. It appears from this account that it is only spores which have shown signs of life, and it seems quite possible that spores of some of the lowly algæ could have survived in a frozen condition for a very long time. From the account it appears that blue-green algæ may be some of the plants which have developed —possibly some of the unicellular green algæ also. As to the grass-like plants which are mentioned, they might well have retained their general appearance in a frozen condition for a very long time, as the ice would preserve the form perfectly well. One would not expect them to have any life in them and this does not appear to have been the case.

Native View of Baganda Institutions

AN account by an African of his own institutions must normally, though not invariably, have an exceptional value for the ethnographer. Being as a rule a spontaneous production, it avoids the great danger of the usual method of inquiry, in which there is the risk of biasing the sources of information. Sir Apolo Kagwa, the *Katikiro* of Uganda, who produced in 1918 an account of Baganda history and institutions in his native language, was exceptionally well qualified for this undertaking. A man of considerable intellectual power, he had been associated with the royal household from his early youth, and when in 1897 the young Daudi Chwa, an infant, one year and six months old, was appointed king on the abdication and flight to German East Africa of his father, Mwanga, Apolo was made regent and prime minister. He thus had a personal and intimate knowledge of the critical times which led up to the intervention of the British forces in Uganda and the institution of a protectorate. His authority on State affairs and ritual is beyond question. One of the most valuable records he has preserved is that of the officers and queens of each ruler from the beginning of the line with the semi-legendary founder Kintu. The Rev. J. Roscoe, when collecting information for his book "The Baganda", derived a great deal of his material from the *Katikiro*; and, in fact, Sir Apolo's book, which is an invaluable, and indeed a necessary, supplement to Roscoe, was written to expand and correct what he considered to be open to criticism in the work of the latter. The fact that Sir Apolo wrote in Luganda has proved a drawback; but this has now been remedied in a translation by Ernest B. Kalibala, edited by May Mandelbaum (Edel) (*Columbia University Contributions to Anthropology*, 22, 199. 4 dollars). For the convenience of students the mere repetitions of Roscoe's information are omitted, but references to "The Baganda" are given here as well as where Roscoe is supplemented or corrected.

Safety in Mines Research

As in past years, the Fourteenth Annual Report of the Safety in Mines Research Board includes a report of the Health Advisory Committee, which forms in fact Part 4 of the Report, the previous parts being Part 1, General; Part 2, Instruction; and Part 3, Progress of Safety Researches. The Report, of course, begins with an expression of regret on the death of Dr. J. S. Haldane, who "had been a member of the Board since 1923"; there is not a miner who will not re-echo the last sentence of the first paragraph in reference to Dr. Haldane—"His death is a severe loss to the whole mining community"; whilst it also refers to the retirement of Prof. S. M. Dixon, who, as is well known, has rendered much valuable service in connexion with wire ropes used in mining. There is further a number of appendixes to the Report, one of which deals with protective equipment, and it is interesting to note that, generally speaking, protective equipment has been largely adopted by the miners themselves. It is worth knowing that Great Britain is not the only country adopting protective equipment, the article by Leprince-Ringuet on miners' hats appearing in the *Annales des Mines* of Paris proving this point. The various representatives of the local committees are doing good work in popularizing the use of protective equipment, and the subject of falls of ground is making fair progress, considering the inherent difficulties of the subject.

Radio Relay Services

RADIO relay is much more common abroad, where it is regarded as a public service, than in Great Britain. In a pamphlet written by G. S. Lucas and E. S. Hall of the Research Department of the British Thomson-Houston Co., Ltd., a description is given of the radio relay equipment built and designed for the Midland Relay Services, Ltd. It is suitable for 300 subscribers but could easily be adapted to suit 1,000 or more subscribers. It has four radio receivers with their aerial equipment, and a short-wave receiver. The aerial equipment depends upon the locality and conditions of reception. For the installation carried out at Rugby, two vertical aerials about 25 feet in length are used for local reception. For long-distance work a horizontal aerial 100 feet long and 50 feet high is used. For use on short-wave reception a special *V* doublet aerial has been installed. Two of the receivers are suitable for B.B.C. transmission and two for long-distance Continental programmes. The advantages offered to the public by this service are the replacement of aerials by simple overhead wires. The installation of only a simple speaker unit in the house is required; no power supply or battery is necessary. The main control station is under constant supervision and the receivers are adjusted for the best working conditions. The radio relay station is capable of relaying two or three independent programmes to all subscribers. All the vital points of the system are duplicated and the organization can deal quickly and effectively with faults and complaints as they arise.

Telephone Development in Birmingham

A LARGE and imposing building called Telephone House has been built in Birmingham to accommodate the telephone equipment for the city and also the Post Office and engineering and administrative staffs. A description of the telephone equipment required for the trunk, toll and central exchanges which were installed by Siemens Brothers and Co., Ltd., of Woolwich, to the order of the Post Office, is given in the September supplement of the *Siemens Magazine*. The introduction of the maximum fee of one shilling for three minutes on all inland trunk calls made after 7 o'clock in the evening has made the trunk service very popular, and the more recent introduction of a half-crown maximum for a three minute trunk call between any two places on the mainland of Great Britain will still further increase the amount of trunk traffic. Outside London, Birmingham is the most important telephone centre in Great Britain. It is connected by direct trunk lines with all other zone centres and, in addition, forms an important link in the alternative trunk routes between London and other zone centres such as Liverpool, Manchester, Leeds, Sheffield, Nottingham and Leicester. The new trunk and toll equipment has been planned to meet the long distance (trunk) and the short distance (toll) traffic anticipated in the Birmingham district during the next few years. Since 1930 the development of the trunk traffic has exceeded all expectations. There have been installed in the building 367 switchboards, and in addition a centralized manual board for the whole of the Birmingham area. In the same building also a 5,700 line full automatic equipment for the central exchange is being installed. Two motor generator sets driven from the 400 volt 3 phase 50 cycle public supply mains, with an output of 1,600 amperes at 57 volts, are being used.

Research in Mental Diseases

THE Annual Report, 1935–36, of the Joint Board of Research for Mental Disease of the City and University of Birmingham contains an account of much painstaking and laborious work (Birmingham: The University, 1936). The occurrence and distribution of 80 named varieties of micro-organisms are tabulated; 6,565 specimens were examined. Somewhat optimistically the report claims to have solved the problem of the cause of mental disease, since "it appears that mental disorder cannot be classed as an infectious disease, nor as a metabolic disorder, but that it is a *clinical resultant* of infectious and metabolic disorders acting during any period of the ante- and post-natal life of the individual, thus determining the character and onset of the mental symptoms". Also, "The functional disturbances of the central nervous system responsible for the symptoms of mental disorder, can be clinically and pathologically associated with local disturbances of the vascular supply to certain vital centres of the brain". It is true that the pathology of some brain diseases that cause mental disorder is well established, for example, encephalitis, syphilis, tumours; but there still remains a host of disorders, ranging through hysteria and the anxiety and obsessional states to schizophrenic personalities, and cyclothymia or manic-depressive conditions and paranoia, that have so far defied the laboratory expert.

False Killer Whales in South Africa

DR. LEONARD GILL, in the Report of the South African Museum for the year 1935 (1936, p. 10), recounts another of those mass strandings of *Pseudorca crassidens* which have become so frequent since the reappearance of the species in the Dornoch Firth. The school came ashore at Mamre, about fifty miles north of Cape Town, and the occurrence was peculiar because of the large number of whales stranded, about three hundred, and because they came ashore not on sand but on jagged rocks. But a common feature of the strandings has been, as here, that the whales appear to have been trapped by a falling tide in channels cut off from the open sea by sand-banks. The Mamre stranding took place towards the close of 1935, and seven years before, about the same time of the year, the first record of the species in African waters was made when about a hundred came ashore at Kommetjie, some sixteen miles south of Cape Town.

Canadian Reindeer Herd

THE introduction of a herd of reindeer to Canada as an addition to the food resources of the far north has met with success. Notwithstanding the severity of the winter, the herd on its winter range east of the delta of Mackenzie River in the Northwest Territories is reported by the Office of the High Commissioner to be in good condition, and to number about 3,000. Surplus males to the number of 200 were slaughtered during the autumn and the carcasses used for food, while the hides were used for moccasins, mittens and other items of wearing apparel. The herd, accompanied by its herders, undertakes a regular north and south migration, moving northward along the arctic coast early in April and southward again in late autumn, grazing by the way over the hills and valleys of its reserve of 6,600 square miles.

American Research Grants

PART 3 of volume 76 of the *Proceedings of the American Philosophical Society* contains the report for the first three years of its operation of the Committee on Research established by the Society. The Committee set apart 20,000 dollars in 1933, 45,000 dollars in 1934, 60,000 dollars in 1935, and 50,000 dollars in 1936. Ninety-eight grants have been made of the average value of 1,500 dollars: sixteen in zoology, fourteen each in physics and botany, ten in astronomy, nine each in geology and physiology, six in chemistry, five in archæology and smaller numbers in other subjects. These grants are more generous than those made by the National Research Council but are less than those made by some of the great foundations. The Committee proposes to hold each year an autumn meeting at which the reports of grantees as to the progress of their researches will be read. The Committee would welcome suggestions for improving its methods of aiding research.

Research Grant Board, South Africa

THE recently issued report of the Research Grant Board, Union of South Africa, covers the period 1918–35. The Board was established in October 1918 as a result of a recommendation of the Advisory Board of Industry and Science, which had been formed earlier that year from an amalgamation of the Industries Advisory Board and "a Scientific and Technical Committee". It was at first proposed that the Research Grant Board should be attached to the Department of Agriculture, but after forming a sub-committee of the Advisory Board until the dissolution of the latter in 1923, it was attached to the Department of Mines and Industries until 1933, when it was transferred to the newly-formed Department of Commerce and Industries. While attached to one Department, the Board is regarded as serving all branches of Government, recognition being given to this relationship by the presence on the Board of assessor members from other Departments. Initially, the Board's activities were confined to the encouragement of research in universities and museums, but its scope was speedily extended to embrace every branch of knowledge and to include the whole country irrespective of institutions.

ONE of the most important functions of the Board is the administration of Government grants in aid of research as well as research scholarships. It has also undertaken similar duties on behalf of the Carnegie Corporation of New York, which has allocated generous funds for research in South Africa. As at first constituted, the Board consisted of representatives of science and industry, together with the assessor members from Government Departments. When its scope was enlarged, members were added to represent other than scientific subjects. While ordinary members of the Board have been chosen with an eye to representation of all the interests concerned, they are regarded as serving wholly in their individual capacity and responsible only to the Minister. The success and efficiency of the Board are attributed largely to this arrangement and to the spirit of unity it engenders, and also to the excellence of its personnel and the unstinted manner in which they have given of their best to the work.

Carnegie Institution of Washington

THE report of the president of the Carnegie Institution of Washington for the year ending October 31, 1935, refers to developments in methods and organization of research in the Institution, particularly in the support of larger projects and the co-operation of fair-sized groups of individuals, as in the Geophysical Laboratory, Mount Wilson Observatory and the Department of Genetics. Its present organization is adapted not only to the advance of knowledge in new interlocking or overlapping areas of research, but also to bring back to each of the groups engaged upon special problems a wide range of materials otherwise not readily secured. Reference is made in the report to the progress of seismological research and of the investigations on terrestrial magnetism. Astronomical work has included study of the nova in Hercules, of stellar atmospheres, extra-galactic nebulæ, measurement of the velocity of light and observations of sunspot activity. Assistance has been given to research on cosmic rays and on the hydrodynamics of the atmosphere and major climatic variations. Numerous investigations have been carried out by the Department of Plant Biology, including the study of the influence of climatic environment on the life and development of living organisms, and by the Division of Animal Biology which includes the Department of Embryology, the Nutrition Laboratory and the Department of Genetics. Of outstanding interest are the activities of the Division of Historical Research, established in 1929, which has provided the opportunity to study history as science, art, culture, sociology and government in all phases with the application of scientific principles to the collection of materials and to the interpretation of the data acquired. The rapprochement of scientific and cultural or human interests in this way is an outstanding achievement of the Institution.

Conference on College Hygiene

THE second National Conference on College Hygiene of the United States will be held in Washington, D.C., on December 28–31 under the joint sponsorship of the American Student Association, the National Health Council and the President's Committee of Fifteen on College Hygiene. There will be no formal programme, but the work will be divided into five sections devoted respectively to health service, health teaching, organization and correlation, special problems and relationship of college hygiene to training and secondary education. Dr. Livingston Farrand, president of Cornell University, from whom further information can be obtained, is chairman of the Conference.

Indian Science Abstracts

THE National Institute of Sciences of India has recently issued the first number of *Indian Science Abstracts*, an annotated bibliography of science in India, including abstracts of all papers published in India or abroad on work done in India or based on Indian material. The first part includes abstracts arranged tentatively under nine headings. To ensure continuity under each heading and to facilitate reference, the abstracts dealing with each science have been given a separate pagination with the serial number of the heading preceding it. The abstracts in each section are arranged alphabetically and numbered serially. The general editor is Dr. Baini Prashad, who is assisted by nine associate editors for different subjects.

Announcements

DR. HANS VON EULER-CHELPIN, professor of organic chemistry at Stockholm, has been elected an honorary member of the Association of German Chemists; the Justus Liebig Medal of the Association has been awarded to Dr. Gustav Hüttig, professor of inorganic and analytical chemistry at the German Technical University at Prague; and the Carl Duisberg Memorial Prize to Dr. Rudolf Tschesche, of Göttingen.

A PRIZE of 1,000 dollars is offered by the Williams and Wilkins Publishing Company for the best work on a science subject presented before July 1, 1937. The work must be in English and the desired length is 100,000 words. Further information can be obtained from the Company, Mt. Royal and Guilford Avenue, Baltimore, Maryland.

DURING the forthcoming winter, Mr. H. V. Garner, the guide demonstrator of the Rothamsted Experimental Station, Harpenden, Herts, and other members of the staff, are prepared to give a few lectures to chambers of agriculture and horticulture, farmers' clubs, farm workers' associations, agricultural societies, etc., on the Rothamsted experiments. Among the subjects offered are: manures, fertilizers, soil micro-organisms (Bacteria, Protozoa, etc.), agricultural botany, agricultural chemistry, soil physics, entomology, and plant pathology. Further information can be obtained from the Secretary, Rothamsted Experimental Station, Harpenden, Herts.

MR. W. J. HALL, of Walsall, who was formerly with the Wool Industries Research Association at Leeds, and later with British Celanese Ltd., has been appointed technical editor of the *Journal of the Textile Institute*.

MESSRS. ADLARD AND SON, LTD., presented to members of the British Association at Blackpool a handy pocket diary, the main part of which consists of a calendar (September 1936–July 1937) of the meetings of scientific societies. Copies of the little book can be obtained from Messrs. Adlard at 21 Hart Street, London, W.C.1, price 6*d*.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A principal of Llanelly New Mining and Technical Institute—The Clerk of the Education Committee, County Education Offices, Carmarthen (September 28).

An assistant lecturer in mathematics in the Huddersfield Technical College—The Director of Education, Education Offices, Peel Street, Huddersfield (September 30).

An assistant lecturer in metallurgy in University College, Swansea—The Registrar (September 30).

An assistant (Grade III) in the Air Ministry Scientific Pool, for service at the Royal Aircraft Establishment, South Farnborough—Chief Superintendent, Royal Aircraft Establishment, quoting Ref. A.248 (October 2).

An assistant keeper on the higher technical staff of the Science Divisions of the Science Museum—The Director, Science Museum, South Kensington, London, S.W.7 (October 12).

An assistant county dairy instructor for Hampshire—County Agricultural Organizer, The Castle, Winchester (October 12).

A chemist in the Aeronautical Inspection Directorate Test House, Kidbrooke (non-metallic materials section, oils and petrols sub-section)—Secretary, Air Ministry (S.2.d.), Adastral House, Kingsway, W.C.2 (October 24).

A director of the Kanematsu Memorial Institute of Pathology, Sydney Hospital, N.S.W.—Secretary, Universities' Bureau, 88a Gower Street, London, W.C.1 (January 31).

Assistants to civil and mechanical engineers in the Ordnance Factories, E.D.(F.), Royal Arsenal, Woolwich, S.E.18—The Chief Superintendent.

A male junior assistant chemist at the Royal Gunpowder Factory, Waltham Abbey, Enfield Lock, Middlesex—Principal Clerk.

Temporary assistant civil engineers in the Air Ministry—Secretary (W.B.9), Room 712, Adastral House, Air Ministry, Kingsway, W.C.2, by post-card for form of application.

A male laboratory assistant (Grade II) at the Experimental Station, Porton, near Salisbury, of the War Department—Commandant of the Station.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 552.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Oxygen Content of the Stratosphere

AIR from different heights of the stratosphere was brought down by registering balloons by means of a new device for air sampling. As the apparatus was protected against the low air temperature in the stratosphere by a "Cellophane" case, it was possible to employ ordinary stop-cocks. At the desired heights the latter were operated by an electrical arrangement actuated by aneroids. The glass vessels for air sampling were constructed so that the oxygen content could be determined in them by means of heating metallic copper without it being necessary to change the vessel. Before and after heating the copper the volume was brought to the same level, so that the diminution of pressure divided by the initial pressure immediately gives the oxygen content.

The following table gives the values obtained for the oxygen contents :

Date	Height (km.)	Oxygen content (per cent by vol.)
24. 8.36	0	20·92 ± 0·02
19.12.35	14·5	20·89 ± 0·05
5.12.35	18·5	20·84 ± 0·02
18. 8.36	19	20·87 ± 0·02
5.12.35	22·2	20·57 ± 0·05
12. 2.36	24	20·74 ± 0·02
6. 5.36	28–29	20·39 ± 0·05

In approaching the height of 20 km. the oxygen content is diminished noticeably in comparison with the value at the earth's surface (20·90–20·95 per cent); above 20 km. the diminution begins to be more pronounced; at the greatest height there is a deficit of 2–3 per cent of the oxygen content. The values agree with the determination of the helium content of the stratosphere by F. Paneth[1], who at a height of 21 km. finds a helium surplus of 8 per cent.

It is remarkable that at heights greater than 20 km. the values differ rather considerably. This is probably due to the weather conditions. In air masses of polar origin it seems that the diffusive separation begins at lower heights than in equatorial regions where the top of the troposphere is remarkably higher. The insolation in equatorial regions is very much stronger, and the turbulence of the atmosphere reaches to greater heights. Lepape and Colange[2] also find that the content of helium plus neon in the stratosphere is slightly increased, and more variable than on the earth's surface. If my assumption is true, then the height of the ozone layer in the stratosphere should also be lower in polar regions than in equatorial regions, first, because the oxygen content in polar regions decreases with heights more rapidly than in equatorial regions, and secondly—which is perhaps of even greater effect—because the greater stability of the atmosphere in the polar regions tends to increase the diffusion of the heavy ozone downwards.

A more detailed report will be published shortly in *Luftfahrtforschung*.

Absence of Cosmic Rays from Nova Lacertæ

THE appearance of Nova Lacertæ gave us a second opportunity of investigating whether the conclusion at which we arrived when investigating the relation of Nova Herculis to cosmic rays[1], namely, that no cosmic rays emitted from novæ are observable, was correct or not. For this purpose we have turned the centre line of the field of our apparatus (field of the apparatus: 40° in east-west, 10° in north-south direction; 36 cm. lead between the counters) as soon as the outburst of the nova was signalled, into such a position that the centre line showed only an angle of 2° 09′ north of the nova at culmination. In such a position a set of measurements was performed from June 19 until July 17, 1936.

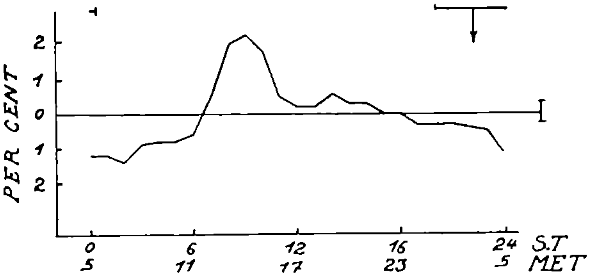

FIG. 1. Variation of cosmic ray intensity (average values) with sidereal time (S.T.) and Central European time (M.E.T.). The horizontal straight line above the diagram indicates the time during which Nova Lacertæ passed through the field of our apparatus, and the arrow the time of its culmination.

Fig. 1 shows the average variation of the intensity for the different hours of the day, as a percentage of the mean value. As can be easily seen, the curve indicates only the well-known diurnal variation, and no increase at the time of culmination of the nova. The assumption that no effect of the nova was detectable, because its cosmic radiation was of much shorter period than the duration of the measurement, cannot be maintained, for even the ratio of the intensity during the culmination of the nova for a single day to the mean value of the daily intensity in no case exceeded twice the error of measurement.

This confirms our previous experience with Nova Herculis, as in neither case could an influence of undeflected cosmic rays originating in the nova be detected.

Resonance Levels for Absorption of Neutrons

WHEN a very thin layer of boron is irradiated with slow neutrons, the number of α-particles emitted can be represented by an expression proportional to $\Sigma n^i\alpha^i + P$, where the terms $n^i\alpha^i$ correspond to the nearly homogeneous groups of neutrons absorbed selectively in certain elements; n^i is the number of neutrons having kinetic energy E^i, and α^i is their coefficient of absorption in boron. The most important term represents the group of 'thermal' neutrons, called by Amaldi and Fermi[1] the group C. If we absorb this group in a thin sheet of cadmium, the number of α-particles emitted by boron diminishes by an amount proportional to $a^C n^C \alpha^C$, where a^C is the fraction of the group C absorbed by cadmium. Similarly, let us suppose that we absorb another group, J, in a suitable element; the corresponding decrease of the number of α-particles will be proportional to $a^J n^J \alpha^J$. If, therefore, the relative numbers of groups C and J and the fractions a are known, we can determine the ratio α^C/α^J, which is equal to $\sqrt{E^J/E^C}$. In this way the energy corresponding to the resonance level of the element J can be calculated.

I have used a boron-coated ionization chamber connected to a Hoffmann electrometer. The chamber was surrounded with paraffin wax and irradiated with slow neutrons from a source of polonium and beryllium equivalent in strength to 10 mgm. of radium. The ionization currents were measured (1) with unfiltered radiation; (2) with neutrons filtered through 0·5 mm. of cadmium; and (3) 0·5 mm. of cadmium and 0·1 mm. of silver. The results are as follows:

Filter	none	0.5mm.Cd	0·5mm.Cd+0·1mm.Ag
Ionization	4·0465	0·3285	0·3145

Owing to the smallness of the effect due to absorption of neutrons in silver, a very great number of measurements has been made so that the statistical errors were about ten times smaller than the differences to be measured. We have

$$\frac{a^A n^A \alpha^A}{a^C n^C \alpha^C} = \frac{0{\cdot}014}{3{\cdot}718} = 0{\cdot}00376.$$

The relative numbers of groups A and C and their coefficients of absorption in cadmium and in silver have been determined by Fermi and Amaldi. As it was, however, to be expected that the numbers may depend on the geometrical arrangement, thickness of paraffin, etc., special experiments have been made in order to compare directly $a^A n^A$ and $a^C n^C$. The boron layer has been removed, and a silver foil of 0·05 thickness exposed in its place, all other conditions remaining unchanged. The activity of the foil, due to the isotope of 22 sec. period, was measured by means of a Geiger counter. If a is the activity obtained with unfiltered radiation, b that with neutrons filtered through 0·5 mm. of cadmium, and c that with neutrons filtered through 0·5 mm. of cadmium and 0·1 mm. of silver, then

$$a = 1490, \qquad b = 1134, \qquad c = 344.$$

If r^A and r^C are the fractions of the total number of neutrons absorbed in the silver foil, we have

$$\frac{a^A n^A r^A}{a^C n^C r^C} = \frac{1134 - 344}{1490 - 1134} = \frac{790}{356} = 2{\cdot}2.$$

The fraction r^A/r^C can be calculated using the known values of absorption coefficients of silver for the groups A and C. I find

$$r^A/r^C = 53{\cdot}6, \text{ and hence } a^A n^A/a^C n^C = 0{\cdot}041.$$

According to Amaldi and Fermi, $n^A/n^C = 0{\cdot}016$. Considering that $a^A/a^C < 1$, we see that under the conditions of my experiment, group A appears to be very prominent. This may be due to the special arrangement used, or to the fact that the brass walls of the ionization chamber absorbed a considerable fraction of thermal neutrons. For the ratio of the coefficients of absorption in boron, I find finally

$$\alpha^C/\alpha^A = 0{\cdot}041/0{\cdot}00376 = 10{\cdot}9\ ;$$

and for the energy ratio

$$E^A/E^C = 117\ ;\ E \cong 3 \text{ e.v.},$$

in good agreement with determinations of Preiswerk and Halban[2].

Similar experiments performed with gold have given $E^{\mathrm{Au}} \cong 4{\cdot}5$ e.v. In the case of iodine, using as absorber a sheet of potassium iodide of 1 gm./cm.^{2}, I could not find any diminution of the ionization current. This shows, in agreement with the determinations of other workers, that the resonance level of iodine is essentially higher than that of silver and gold. It should be noticed that Collie[3] has applied a similar method, but obtained definite results only in the case of indium.

Destruction of Supraconductivity by Electric Current and Magnetic Field

BY any change of the magnetic flux through a supraconducting ring a permanent current T is induced, the strength of which can be calculated from the field intensity in the centre of the ring, taking into account the field deformation caused by the magnetic properties of the supraconducting ring.

In Fig. 1, T is plotted against the external field intensity H_t for a ring of tin. This curve, which limits the region of supraconductivity ($\rho = 0$), is given by the condition that the sum of the tangential component of the external field and the field caused by the current is equal to the critical magnetic field, either on the inside or on the outside periphery of the ring, while the field is certainly smaller on the rest of the ring surface. Thus our experiments show that it is a necessary condition of supraconductivity, that the magnetic field is zero in the whole of the volume and its effective tangential component does not exceed the critical value at any point of the surface of the supraconductor.

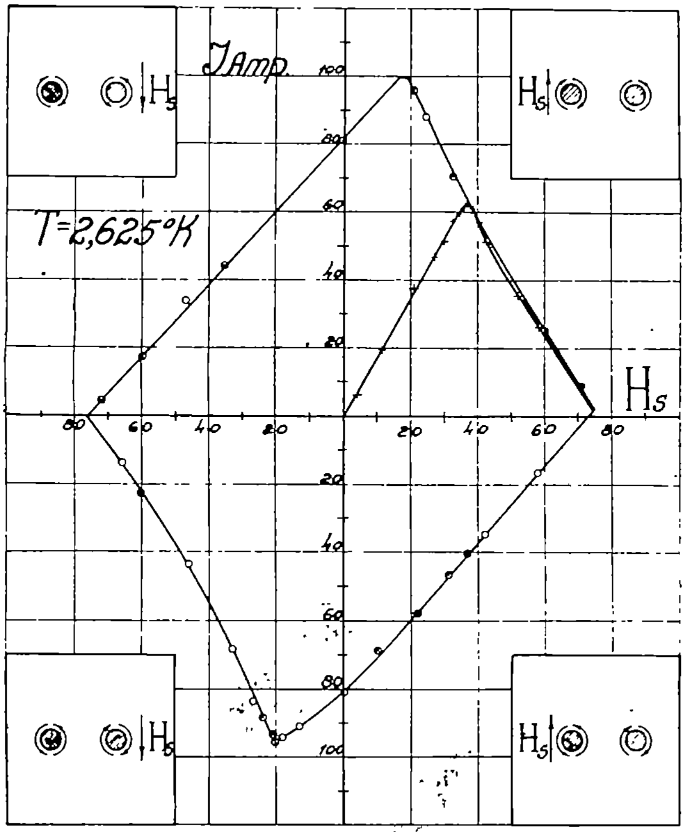

FIG. 1.

In a paper just published by D. Shoenberg[1], the results of measurements on a supraconducting ring of lead are given which are entirely in agreement with our results obtained with tin. But Shoenberg's conclusions are wrong, since he assumes that the decrease in current could be explained by a decrease in the supraconducting cross-section which leads to an unstable condition of current distribution. A more detailed paper on this matter is being published shortly[2].

Influence of Nitric Oxide on the Thermal Decomposition of Dimethyl Ether. Gaseous Catalysis

IN the course of an investigation on the thermal decomposition of dimethyl ether, alone, and in the presence of other gases, the reaction with nitric oxide was studied. We found that very small quantities of the oxide reduced the rate of reaction, represented by the equation,

$$(CH_3)_2O = CH_4 + CH_2O,$$

and measured by the rate of formation of methane, to a very small fraction of the rate observed in the pure gas. This is in accord with the results of Staveley and Hinshelwood[1] in the case of diethyl ether.

As the concentration of the nitric oxide in the reaction mixture is increased, the rate of reaction, which had become very small, increases rapidly. Staveley and Hinshelwood, writing of the reaction in the case of diethyl ether, refer to this process as one of catalysis. In the case of dimethyl ether, however, investigation by the method of detailed analyses shows that catalysis is not involved.

The CH_4–t graphs, representing the rate of primary decomposition of dimethyl ether, bend less sharply towards the t-axis than they should do if the decomposition process followed a normal course in accordance with the classical theory. The graphs show well-marked breaks, and the rate of reaction is diminished by increasing the surface of the reaction vessel. It appears to be an important fact that the process can only follow a single course, and there are no alternatives such as have been indicated in the case of other processes[2].

If a series of experiments is carried out, within the range at which the presence of nitric oxide increases the rate of reaction, such that the initial concentrations of the dimethyl ether and nitric oxide, and the temperature, are constant, and the time is varied, it is found that the whole process has no relation to the process involved in the primary decomposition of dimethyl ether alone. The products are methane, carbon monoxide and dioxide, with very little hydrogen, and, at high concentrations of nitric oxide, carbon monoxide is the dominant product. The form of the $x - t$ graphs is quite different from those recorded in the case of the primary decomposition of dimethyl ether alone. They are convex towards the t-axis, as in the case of the thermal decomposition of acetaldehyde. The processes involved are strongly accelerated.

The processes are obviously oxidation processes, and the observations now recorded support the suggestions put forward in the two letters to NATURE referred to above. It seems that the reaction of nitric oxide with dimethyl ether gives rise to processes, each of which results in the formation of a short-lived intermediate, which can decompose in two different ways. The oxidation processes can be represented by a series of equations, such as,

$$(1)\quad CH_3.O\,CH_3 + O \rightarrow CH_3.O.CH_2OH \begin{cases} CH_4 + CO_2 + H_2 \\ CH_4 + CO + H_2O \end{cases}$$

$$(2)\quad CH_3.O.CH_2OH + O \rightarrow CH_3.O.CH(OH)_2 \begin{cases} CH_4 + CO_2 + H_2O \\ CH_3OH + CO + H_2O. \end{cases}$$

In a series of experiments in which a quantity of dimethyl ether was heated with increasing quantities of nitric oxide for 15 minutes, the proportion $(CO_2 + CO) = 2CH_4$ was reached.

Since the characteristics of these oxidation processes are almost identical with those of the thermal decomposition of acetaldehyde, it is not surprising that nitric oxide does not influence the rate of thermal decomposition of acetaldehyde in the manner observed in the case of dimethyl ether. The so-called catalysis of the thermal decomposition of acetaldehyde by nitric oxide is also probably initiated by oxidation processes. The inhibition of the thermal decomposition of dimethyl ether by nitric oxide is, however, a very important addition to those facts which we have enumerated, which serve to distinguish this process from the thermal decomposition of acetaldehyde. Taking all these facts together, it does not seem possible to distinguish either process as being the only one which is influenced by chain mechanism.

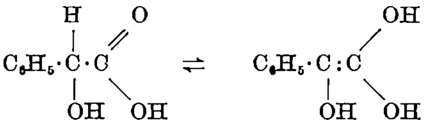
Use of Deuterium as an Indicator in Stereochemical Investigations

1. IT is known that optically active compounds under different influences undergo racemization. Various theories have been put forward to explain the mechanism of these changes.

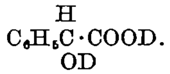
A. Werner[1] took the view that the extreme oscillation of the molecules led apparently to an unravelling of the tetrahedral configuration. Other authors assume that the racemization is brought about through the formation of an enol[2]. Taking as an example mandelic acid, it is assumed that the following equilibrium goes over from the keto-form to the enol-form; that is, there is a change from an asymmetrical to a symmetrical molecule:



The use of heavy water (D_2O) enabled us to decide experimentally between the various opinions, for we know from other examples[3] that the OH group of the enol-forms is exchanged with D_2O. If the racemization in heavy water takes place through the enol-form, then the racemized mandelic acid will show a corresponding high content of the D-atom.

In the control experiment, mandelic acid was recrystallized out of heavy water by heating to 60° C., an operation in which the optical activity is fully retained. The resulting mandelic acid contained, according to isotope analysis[4], $x = 1\cdot7$ D-atom (corresponding to $t = 1\cdot9$)[5], which corresponds to an exchange of two hydrogen atoms.

This result was confirmed by many experiments and is explained by the formation of the acid



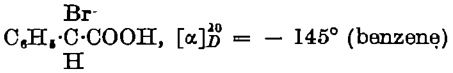
$$C_6H_5\overset{H}{\underset{OD}{C}}\cdot COOD.$$

In the racemization experiment, mandelic acid, dissolved in heavy water, was warmed to a temperature of 140° C. over a period of 51 hours. The acid isolated was optically completely inactive. The isotope analysis of the racemized mandelic acid, carefully purified, freed from all traces of benzoic acid, gave, however, $x = 1\cdot7$, $t = 1\cdot9$ also, corresponding to two interchangeable hydrogen atoms, although if we assume enolization, at least $t = 2\cdot7$ was to be expected. This result, accordingly, is in favour of the Werner-Hund conception of the mechanism of racemization.

A racemization experiment with a mandelic acid in a solution of NaOD also resulted after 16 hours heating at a temperature of 100° C. in a fully racemized acid. Purified and recrystallized from D_2O, the isotope analysis of this acid gives $x = 2\cdot06$, $t = 2\cdot34$.

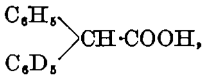
Since the value of t here is again less than $2\cdot7$, it cannot be supposed that racemization and enol formation is the same reaction.

2. There exist the results of a series of experiments concerning the preparation of compounds of the type C.R'R"HD. These communications are partly of negative[7] content and partly positive[8]. In this paper we only want to report on two such experiments. We allowed benzene to react with the optically active compound



$$C_6H_5\cdot\overset{Br}{\underset{H}{C}}\cdot COOH,\ [\alpha]^{20}_D = -145^\circ \text{ (benzene)}$$

in the presence of zinc; the resulting acid,



was optically inactive.

Experiments in which an attempt was made to split up the acid with the aid of alkaloids have also not succeeded in obtaining one isomer from the separated alkaloid salt and its antipodes from the mother liquor. All observed rotation of the plane of polarized light could be traced to impurities. Further experiments are still in process.

However, we have shown with *l*-mandelic acid that the substitution of H by D in an optically active molecule can have an influence on the optical rotation. When *l*-mandelic acid, which is not subject to racemization at 60° C.[9], was allowed to react with heavy water at that temperature, it showed 1·7 D-atoms by the isotope analysis. The measurement of the optical activity of this acid (D) and of the original, untreated *l*-mandelic acid (H), both in dry acetophenone, gave the following results:

	H	D
$[\alpha]^{20}_D$	– 179·10° ± 0 13	– 173 27° ± 0·13
$[\alpha]^{20}_{Hg}$	– 216·34° ± 0·13	– 211·43° ± 0·13

The complete communication will appear in the *Helv. chim. Acta*.

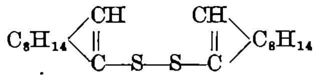
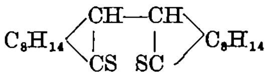
Synthesis of Two Isomeric *bis*-Thiocamphors

In continuation of his researches on thiocamphor[1] reported in this journal, and also published in the *Journal of the Indian Chemical Society*, Mr. D. C. Sen, working in my laboratory, has recently made some interesting observations which, with his views concerning the constitution of the compounds isolated, are reported below.

Bis-thiocamphor has been synthesized by the action of iodine on the sodio derivative of thiocamphor. It may be represented by either (A) or (B).



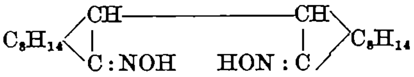
(A)



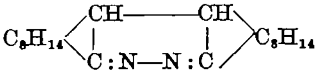
(B)

It has not been possible to synthesize this compound by Oddo's method[2] of synthesis of *bis*-camphor, namely, by the action of sodium or magnesium on β-bromocamphor, as β-bromothiocamphor could not be isolated in the pure state. Incidentally, the synthesis of *bis*-camphor by this method was also tried, but it resulted in the formation of β-iodocamphor instead of *bis*-camphor. *Bis*-thiocamphor has been prepared by the above method in two stereoisomeric forms (*l*- and *dl*-) from *l*-thiocamphor and *dl*-thiocamphor respectively.

dl-*Bis*-thiocamphor, m.p. 164°, forms a dioxine, m.p. 199° (*d*) and an azine, m.p. 176°, whereas *l*-*bis*-thiocamphor, m.p. 180°, also forms an azine, m.p. 200°, under similar conditions. These facts, along with the analytical and molecular weight data of the two *bis*-thiocamphors and their derivatives, lead to the conclusion that they contain two C:S groups, and that they are 1:4-dithioketones, and have the formula (B). The dioxines and the azines should therefore be represented by the structures (C) and (D) respectively.



(C)



(D)

On reduction with aluminium amalgam in moist ethereal solution, *dl*-*bis*-thiocamphor forms *dl*-*bis*-thioborneol, m.p. 148°, which decolorizes iodine and forms a yellow lead salt.

l-*Bis*-thiocamphor has a very high molecular rotation $[M]_D^{20^\circ} = -1109\cdot 5$ in benzene solution, whereas the molecular rotation of *l*-thiocamphor is $[M]_D^{20^\circ} = -41\cdot 3$ in the same solvent, and under similar conditions. This high exaltation in optical activity may be attributed to the presence of a potential conjugated system in *bis*-thiocamphor, which may be effective both in the thio- and thiol- phases.

Studies in absorption spectra in the visible region of *bis*-thiocamphor at different dilutions and the comparison of these with those of thiofenchone and thiocamphor have given interesting results. It has been noticed that a 5·4 per cent solution of bis-thiocamphor in benzene manifests a characteristic absorption band between 5270 A. and 4530 A., and that with dilution this band becomes shorter, and at 2·7 per cent concentration it gives a very short band, having the centre at 4950 A. Similar bands have also been observed in the case of *l*-thiocamphor and *d*-thiofenchone. This selective absorption band is therefore a characteristic property of the C:S group in cyclic thioketones, which is definitely chromophoric.

Further work in this line, which is in progress, will be published in due course in the *Journal of the Indian Chemical Society*.

Non-Existence of Multiplanar Cyclohexane Rings

The work done by us, so far, has shown that it is possible to isolate only two forms of 4-methyl-, 3-methyl- and 2-methylcyclohexane-1-carboxy-1-acetic acids[1] and one form of 3:3-dimethylcyclohexane-1-carboxy-1-acetic acid[2]. In order to get more evidence on the point of the configuration of the cyclohexane ring, we have now synthesized 4:4-dimethylcyclohexane-1-carboxy-1-acetic acid and 4:4-dimethylcyclohexane-1:1-diacetic acid from 4:4-dimethylcyclohexanone. Each one of them is found to exist in one form only, thus supporting the uniplanar structure of the cyclohexane ring. The work is not yet complete, but this notice has been necessary in view of the recent publication of Miller and Roger Adams on the same subject[3]. The full details of the work will be published in due course.

Normal Erosion as a Factor in Soil Profile Development

In Nature of June 6, Prof. G. W. Robinson directs attention to the effects of lateral transport of surface soil material, moved in the course of ordinary slow denudation, on certain soils in Wales. Erosive processes of this kind not only modify the development of particular soil profiles, but also may be found governing the zonation of soil types over wide areas. I offer an example from tropical semi-arid country.

The diagram (Fig. 1) represents, with the horizontal scale much compressed, a residual granite hillock and the soils around it, in the plateau region south of Lake Victoria. Primary soil substance is made among the rocks from the products of mechanical and chemical disintegration of the granite surfaces, together with plant debris, baboon and hyrax droppings, and the like residues. A shallow skeletal dark grey loam (1) is so formed. This works downhill by creep and slow erosion, to serve at the hill foot as the parent material on which a deeper soil (2) of the red earth group develops. At the base of the red earth profile, where there is temporary accumulation of seepage in the wet season, a clinker-like horizon (3), coarse granitic grit in a black and rusty ferruginous cement, begins to form and may in time attain a thickness of a metre or more. In the meantime, occasional storm-water running over the surface is gradually paring off the top soil, and the spoil travels differentially according to particle size, so that by cumulative effect a zone of washed sand (4) covers the footslope below, silty or clayey sand (5, 6) lies beyond it, and a level clay floor fills the bottom-land—the *mbuga* (7). These deposits may, if we will, be looked upon merely as so much parent material, put there geologically by the denudation process; but at all stages, the erosion having been slow and non-catastrophic, they have borne their appropriate vegetation and have been developing towards maturity as soils. At a late stage, as erosion works down towards base level, the abrasion of the red earth profile ends in the emergence of the clinker-like horizon at the lowered ground surface, where (commonly under the misleading name of 'surface laterite') it resists further erosion like the sill of a waterfall in the profile of a stream.

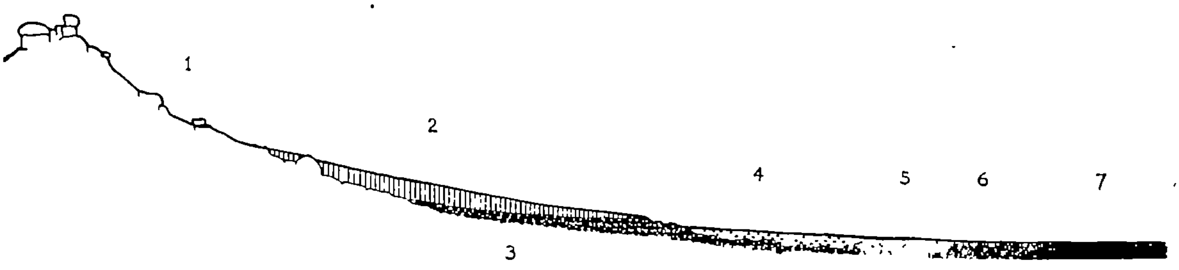

FIG. 1.

A zoned distribution of soil types in relation to the high points in a generally low relief, somewhat as in this example, is found over a great part of the central plateau or elevated peneplain region of Tanganyika. According to the maturity of the topography, or because a new cycle of erosion has been initiated tectonically, or for lithological reasons, the character and proportionate extent of the different soils vary locally, but some six or seven of the main types are of sufficiently general occurrence in their characteristic positions on the contours to have given rise to a well-developed soil nomenclature in the Sakuma language. The complete sequence can be found under seemingly 'virgin' deciduous forest and bush, though there can be little doubt that man has at some time or other usually been in occupation and, as a soil-tilling animal, has expedited the erosive process. The case is not thereby removed from the scope of Prof. Robinson's subject of 'normal' erosion, for primitive man should not be excluded from his due place amongst the natural factors in soil formation.

Does not this example, incidentally, point to an anomaly in the use to which the word *profile* has been put by soil students? To the geomorphologist, geologist or engineer, the profile of the ground would be the outline of my diagram. To the pedologist the profile is what he finds in depth at a selected point. The language of soil description lacks a suitable term having a cross-country dimension, and the want of it is felt as soon as soils are discussed in relation to the lie of the land, as in this matter of erosion. To help in such discussions the word *catena* has been adopted (Provisional Soil Map of East Africa, 1936), to describe a topographic complex of soils such as is represented in my example.

Centrifuging in Rotating Hollow Cylinders

THE method described in this note provides a quick and efficient means for the fractionation of highly disperse systems—including the larger proteins—using relatively moderate centrifugal forces. Furthermore, all necessary information about the sedimentation rate and the sedimentation equilibria of these systems can be obtained, samples for examination being taken before and after spinning. Many important biological agents (viruses, bacteriophages, antibodies, etc.) remained outside the scope of the admirable methods developed by Svedberg because they are not susceptible to direct continuous optical observation, but they are within the range of the new procedure.

The principal points upon which the new method is based are (1) to have the system spread as a thin film on the inner surface of a hollow cylinder rotating with its axis vertical; and (2) to have this film subdivided in two concentric layers, the inner one being liquid, the outer one a gel of a structure sufficiently coarse to permit free motion of the single particles. Thus the distance which the particles have to travel before entering the gel or before reaching the equilibrium distribution can be reduced to a few tenths of a millimetre, whilst the gel-layer provides automatic separation of the 'sediment' from the 'supernatant', or of two levels of the equilibrium distribution, when the rotation is stopped.

In the experimental work done so far, the 'closed bowl' of the Sharples-Super-Centrifuge (inner radius 2 cm., height 20 cm., speed up to 32,000 r.p.m.) has been used without modification. A solution containing 1–2 per cent agar (in water, broth, etc., for simple fractionation, in the suspension itself when sedimentation measurements were intended) was introduced into the warmed bowl and allowed to set with the centrifuge running; the suspension was then introduced, and the spinning continued. Two per cent agar was used for particles less than 20 mμ in diameter and 1 per cent for those less than 60 mμ in diameter.

The assumption of free entrance and motion of the particles in these dilute gels appears to be justified so long as the particles in question are present in sufficiently high dilution, as is the case with most biological agents. With higher concentrations, however, the sedimentation may be hampered by a phenomenon related to the 'blocking' of filters. Therefore—working with serum for example—in spite of the small particle size, 1 per cent agar has been used. That adsorption plays no role in the effects obtained has been controlled by mincing the agar layer in the supernatant: the gel-free filtrate shows again the initial concentration.

The sedimentation in the very thin liquid layers used appears to be quite normal, and the calculation of the rate of sedimentation requires no elaboration here.

When the sedimentation equilibrium is established, the value of k, equivalent to $\frac{N}{RT} \cdot V(\sigma-\sigma_1)g$, in Perrin's equation can be calculated from the measured average concentration, C_S, in the liquid layer, and C_W the average concentration in the whole system, liquid plus gel.

Now

$$C_S = \frac{1}{x_1} \cdot \int_0^{x_1} C_0 \, . \, e^{kx} \, . \, dx,$$

where x_1 = thickness of liquid layer.

x_2 = thickness of gel layer.

C_0 = equilibrium concentration when $x = 0$, that is, at the surface of the liquid.

$$C_W = \frac{1}{x_1+x_2} \cdot \int_0^{x_1+x_2} C_0 \, . \, e^{kx} \, . \, dx.$$

Hence

$$\frac{e^{kx_1}-1}{e^{k(x_1+x_2)}-1} = \frac{x_1}{x_1+x_2} \cdot \frac{C_S}{C_W}, \qquad (1)$$

(x_1+x_2) being considered very small compared with the radius of rotation.

If $e^{kx_1} \gg 1$, then the solution of equation (1) is with good approximation.

$$k = \frac{1}{x_2} \, . \, \ln \, . \, \frac{x_1+x_2}{x} \, . \, \frac{C_W}{C_S}.$$

Otherwise the solution can be made very simple by arranging that $x_1 = x_2$, or that $x_1 = x_2/2$.

Working with the smallest bacteriophage, *S*13, for example, drops of 60–80 per cent in the concentration of the supernatant were found using 2·5 c.c. liquid and a centrifugal force of 10,000 × gravity, in 2–3 minutes time. This leads to a sedimentation constant of about $s = 5 \times 10^{-12}$. The 'molecular weight'—about $2\text{–}3 \times 10^6$—obtained for this phage from the estimation of the sedimentation equilibrium using centrifugal forces of 2,500–10,000 × gravity is in good agreement with the value derived from the sedimentation rate.

In experiments made with Dr. Elford on Type I-pneumococcus anti-serum (horse), 60–70 per cent of the antibody was spun down in thirty minutes (force, 20,000 × gravity); the drop in the total protein content determined refractimetrically was about 30 per cent. No further change was obtained by continued spinning. The calculation from this equilibrium leads to a value of about 4×10^5 for the 'molecular weight' of the antibody (corresponding to the globulin fraction of largest particle size). This confirms previous results obtained by Elford and his collaborators by filtration[1], and recent findings on concentrated purified antibody preparations using air-driven[2] and Svedberg centrifuges[3].

Besides the examples mentioned, the new method is being used in collaboration with Drs. Elford, Galloway and Andrewes for the purification of viruses and for the estimation of the specific gravity of viruses and bacteriophages. Some of the results have been mentioned at the Second International Congress for Microbiology. A more detailed account will be given later.

Regeneration in Arachnida

DURING last year I noticed that Harvestmen (Opiliones) do not regenerate lost legs when they moult, and this summer I have determined that they do not regenerate pedipalpi either. It seemed possible that this surprising deviation from a general character of the Arachnida might be related to the contrast between the length of the limbs and the shortness of the cephalothorax, within which it would be impossible to develop a leg long enough to be useful when exposed by ecdysis, and that, if this were so, the same peculiarity might be shown by spiders with very long legs. A specimen of the spider *Pholcus phalangioides*, sent to me by Dr. W. S. Bristowe, has just cast its skin and shows no trace of a new leg to replace one which I removed four weeks ago.

Such failure to regenerate is, I think, a previously unrecorded feature among Arachnida, and it is intended to repeat the investigation with other spiders, such as *Phyllonethis* and *Tetragnatha*, which also have long legs.

Chromosome Number of *Eucalyptus globulus* and *Eucalyptus Johnstoni*

WE have endeavoured to determine the chromosome numbers of certain species of *Eucalyptus*, using radicles, root tips and anthers. Although clear-cut mitotic figures were obtained with radicles and root tips, consistent with one another under different conditions of fixation and staining, we were not successful in determining the chromosome number with certainty, owing to the tendency of the chromosomes to remain attached to each other throughout the cycle.

Greater success was achieved with pollen mother cells, although here also the above tendency was to some extent troublesome. Diakinesis gave the most unambiguous results, but checks were obtained with metaphase I and anaphase I.

The haploid number for both *E. Johnstoni* and *E. globulus* is eleven. There appears to be an interesting tendency to secondary pairing in *E. globulus* which makes the determination of the number in metaphase I and anaphase I less certain than with *E. Johnstoni*; but the diakinesis figures seem conclusive.

Work is proceeding with the view of tracing the course of the whole meiotic series of changes. These show interesting variations from the normal.

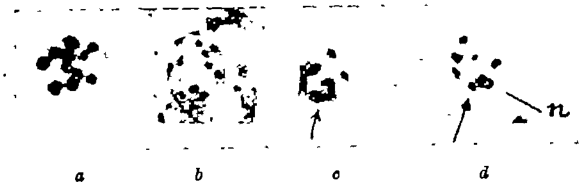

FIG. 1. (*a*) Metaphase I of *E. Johnstoni* × 2000. (*b*) Late diakinesis of *E. Johnstoni*. Two photographs of the same cell, focused on different planes, are superimposed. The nucleolus has disappeared. × 1000.

(*c*) and (*d*) Two photographs of the same cell in early diakinesis (*E. globulus*) The nucleolus is seen in (*d*) in close conjunction with a chromosome (*n*). The chromosome marked by the arrow appears in both photographs. × 1000.

Figs. 1 *a* and *b* show a typical metaphase I, and a composite photograph of diakinesis in *E. Johnstoni*; figs. 1 *c* and *d* are two photographs focused on different planes in a nucleus in diakinesis in *E. globulus*.

Our best thanks are due to the trustees of the Science and Industry Endowment Fund for a grant, without which this work would not have been possible.

Carbohydrate Metabolism

EXPERIMENTS which have been in progress in this laboratory during the past six months have had results very similar to those described by Krebs[1] in a recent letter. The formation of α-ketoglutaric acid in the course of pyruvic acid oxidation was made very probable by my earlier results[2]. In recent experiments the formation of succinic acid from pyruvic acid, acetic acid and α-ketoglutaric acid could be demonstrated both anærobically in minced brain and ærobically in the minced brain poisoned with malonic acid. Two explanations of these facts are possible: (1) there are two alternative paths of succinic acid formation from pyruvic acid, one leading to α-ketoglutaric acid by the condensation of two molecules of pyruvic acid and subsequent decarboxylation[2], the other starting with decarboxylation of pyruvic acid to acetic acid and subsequent condensation of two molecules of acetic acid[3]; (2) α-ketoglutaric acid is formed by condensation of one molecule of pyruvic acid and one molecule of acetic acid. It has not yet been possible to decide which is correct.

The decarboxylation of α-ketoglutaric acid by brain slices under anærobic conditions depends on the presence of suitable hydrogen acceptors. The carbon dioxide evolution is increased on addition of a neutralized dye (Brillant cresyl blue) and reduced to the initial value as soon as the dye is decolorized (Fig. 1). The carbon dioxide evolution due to the reduction of the dye[4] is very small in the case of Brillant cresyl blue and can easily be allowed for. The amount of carbon dioxide given off by decarboxylation of α-ketoglutaric acid is almost exactly equivalent to half the amount of the added dye. Since two molecules of dye correspond to one molecule of oxygen, the *R.Q.* under these conditions is 1, the same as in ærobic experiments. Since the amount of hydrogen acceptor is the limiting factor of the decarboxylation, it is concluded that a dehydrogenation precedes the decarboxylation, thus excluding the possibility of an aldehyde as intermediate. In analogy to the oxidative deamination, the following mechanism of decarboxylation may be suggested:

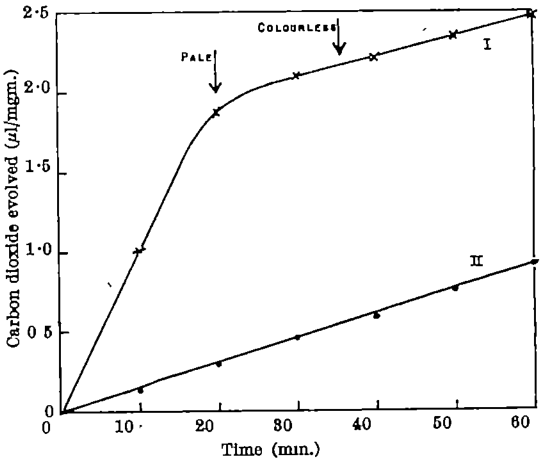

FIG. 1. Carbon dioxide evolution by slices of guinea pig brain in nitrogen in presence of *m*/50 α-ketoglutaric acid; I, after addition of Brillant cresyl blue (0·15 ml. of *m*/50 sol.; carbon dioxide corrected for the amount due to reduction of the dye); II, without Brillant cresyl blue.

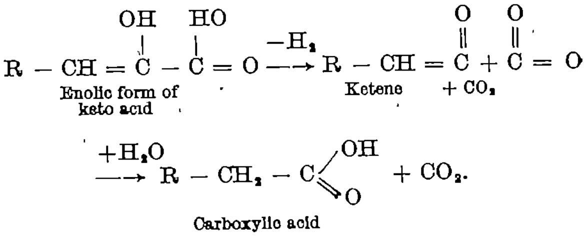

$$\underset{\text{Enolic form of keto acid}}{\mathrm{R-CH}=\overset{\mathrm{OH}}{\overset{|}{\mathrm{C}}}-\overset{\mathrm{HO}}{\overset{|}{\mathrm{C}}}=\mathrm{O}}\xrightarrow{-\mathrm{H_2}}\underset{\text{Ketene}}{\mathrm{R-CH}=\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}}+\underset{+\,\mathrm{CO_2}}{\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}=\mathrm{O}}$$

$$\xrightarrow{+\mathrm{H_2O}}\underset{\text{Carboxylic acid}}{\mathrm{R-CH_2-C}\begin{matrix}\diagup\mathrm{OH}\\ \diagdown\mathrm{O}\end{matrix}}+\mathrm{CO_2}.$$

Glucose, which provides suitable hydrogen acceptors, can replace the dye, as shown by anærobic succinic acid formation from α-ketoglutaric acid. Pyruvic acid liberates carbon dioxide and forms succinic acid anærobically even in absence of glucose or other hydrogen acceptors, no doubt because it acts itself as hydrogen acceptor, being partly reduced to lactic acid. The system β-hydroxybutyric acid⇄acetoacetic acid, quoted by Krebs, is only one of many reversible oxidation-reduction systems in the cell, which act as reserve hydrogen acceptors guaranteeing the progress of vital oxidations independently of the varying oxygen supply.

KREBS[1] stated recently that vitamin B_1 is a co-enzyme for two anærobic reactions, of which one is the following:

$$\alpha\text{-ketoglutaric acid} + \text{'ketonic' acid } (A) + H_2O \rightarrow \text{succinic acid} + CO_2 + \text{'hydroxy' acid} \ldots (3)$$

where the reaction is common to carbohydrate metabolizing animal tissues, and where A can be pyruvic acid; the ærobic oxidation of pyruvic acid is considered to be preceded by an anærobic stage.

These conclusions would not seem to be general for the following reasons. We happen to have tested Krebs's reaction 3 already among others, using avitaminous pigeon's brain tissue in presence and absence of vitamin B_1. Our tests were ærobic, but they cover the point because any succinic acid formed should be detectable by an increased oxygen uptake in the presence of the abundant succinoxidase present. No increased (or decreased) vitamin B_1 effect was observed by adding α-ketoglutaric to pyruvic acid. Hence in our brain systems, the extra oxygen uptake catalyzed by vitamin B_1 in presence of pyruvic acid does not follow the lines of the above equation.

We are not yet in a position to make a statement about Krebs's reaction (1) as regards our system; but we can say that we have definite evidence against the view that the oxidation of pyruvic acid proceeds through the stage of succinic acid, which has been suggested for muscle[2] and for kidney[3].

Points from Foregoing Letters

THE content of oxygen by volume at high altitudes, obtained by means of registering balloons with a new device for air sampling, is found by Prof. E. Regener to decrease from 20·9 per cent at 14 km. to 20·4 per cent at 28 km. At heights above 20 km. there are relatively great variations in composition, due probably to weather conditions.

No increase in the normal amount of cosmic rays that could be attributed to the appearance of Nova Lacertæ was observed by Drs. J. Barnóthy and M. Forró between June 19 and July 17 on pointing their 'counters' towards the new star at its highest position in the sky.

The ionization current due to slow neutrons produced in a boron-coated chamber has been measured by J. Rotblat in absence and in presence of absorbers of cadmium, silver, gold and iodine. The diminution of the ionization current for each element is proportional to the number of neutrons selectively absorbed in this element, and to their coefficient of absorption in boron. Assuming that this coefficient is inversely proportional to the velocity of neutrons, and that the 'cadmium' neutrons possess thermal energies, that is 0·025 e.v., Mr. Rotblat finds that the 'silver' neutrons have an energy of about 3 e.v., the 'gold' neutrons about 4·5 e.v., and that the energy of 'iodine' neutrons is essentially higher.

By plotting the strength of the current induced in a supraconducting ring of tin against the field intensity, L. Shubnikov deduces, as a necessary condition of supraconductivity, that the magnetic field should be zero in the whole of the volume and its effective tangential component should not exceed a critical value at any point of the surface of the supraconductor.

Small quantities of nitric oxide reduce the rate of thermal decomposition of dimethyl ether, but larger quantities increase it. P. F. Gay and Prof. M. W. Travers find that the end products in the two cases are different, and they consider that the effect observed with nitric oxide cannot be attributed to catalysis. They postulate the formation of short-lived intermediates.

Mandelic acid loses its optical activity (becomes 'racemized') when heated at 140° in heavy water. Prof. H. Erlenmeyer, H. Schenkel and A. Epprecht find that the number of heavy hydrogen atoms which replace ordinary hydrogens in the mandelic acid molecule during this transformation supports the Werner-Hund conception of the mechanism of racemization. They also report the influence of the heavy hydrogen on the optical activity of the mandelic acid.

The properties and reactions of two sulphur-containing camphor derivatives (*l*- and *dl*-*bis*-thiocamphor), synthesized by D. C. Sen, are reported by Sir P. C. Rây.

An example of the effects of slow erosive shift of surface soil material on the zoning of soil types around high points in a region of peneplain topography is adduced by G. Milne from the central plateau of Tanganyika Territory. Comment is made on the use to which the word *profile* has been put in soil terminology.

Dr. M. Schlesinger describes the use of hollow cylinders coated with a thin gel layer, and rotating with the axis vertical, for the study of systems of high dispersity. The distance which the particles have to travel being reduced to a few tenths of a millimetre, the effect of a given centrifugal force is increased many hundredfold if compared with usual conditions. The use of the gel provides satisfactory separation of 'supernatant' and 'sediment', and the possibility of estimating sedimentation rates and equilibria on substances not subject to direct optical observation. The method is proving particularly useful for the study of biological agents (viruses, bacteriophages, antibodies).

Photomicrographs of pollen mother cells of *Eucalyptus Johnstoni* and *E. globulus* are submitted by Prof. A. L. McAulay, F. D. Cruickshank and R. G. Brett; they show that the haploid number of chromosomes for both those species is eleven.

Dr. H. Weil-Malherbe reports the formation of succinic acid from pyruvic, acetic and α-ketoglutaric acids by brain tissue, both under anærobic and ærobic conditions. It is claimed that decarboxylation is an oxidative process, with ketene as possible intermediate. The reversible oxidation-reduction systems in these reactions are held to function as reserve hydrogen acceptors, which may replace oxygen.

Research Items

Population of the Northern Plains Indians

DR. CLARK WISSLER has made a study of the size of certain American Plains Indians tribes during the period of the fur trade and under the reservation system (*Yale Univ. Publications in Anthropology*, No. 1). He reviews the available data in time sequence, dealing with the Blackfoot group, the Assiniboin, and the Western Cree, who became Plains Indians before the close of the fur trade period, and then wandered about, like the Assiniboin, in bands. The fur trade period is taken as extending from 1670 to 1870. Certain general conclusions emerge. There were repeated expansions into the area of the Northern Plains, largely by Algonkin speaking tribes, such as the Blackfeet, Arapaho, Gros Ventres, etc. These expansions seem to have had a common source. The Blackfeet, apparently, were the first. The Gros Ventre held most of the Saskatchewan area in 1754, but then began to retract, when the Assiniboin were expanding into the area. These reached their maximum in 1830. The great expansion of the Cree began about 1800 and culminated in 1875. The study of population suggests that these expansions were accompanied by an increase in population; and when the tribes retracted, population shrank. The expansions from the Lake country were not all in historic times and not all due to white pressure. The coming of the horse, firearms and the expansion of the fur trade were stimuli. Diminishing returns in buffalo and fur began about 1850. The disappearance of the buffalo and the taking up of reservation life were severe blows to numbers and culture. However, recovery set in at an early date, and a few tribes seem to have suffered little population loss. The reservation system may be considered a stabilizer, and saved many tribes from destruction. Instead of proving a quick method of absorbing the Indian, as was anticipated, it has proved the reverse. At present the national Indian policy is to conserve tribal culture rather than to destroy it.

Fossil Men of Engis

A RE-EXAMINATION by Dr. Charles Fraipont of the evidence relating to the discovery by Philippe Charles Schmerling in 1830 of two human skulls associated with a fossil fauna and flint implements in caves at Engis, near Liège, has established the fact that Schmerling was the first to discover an example of Neanderthal man (*Archives de l'Inst. Pal. Humaine, Mém.*, 16). The first skull, the only one described hitherto, is well known as a member of the Cro-Magnon race, but of a less specialized type, belonging to the group Brnŏ, Vistonič and Combe-Capelle. The second, however, never previously described, is now shown to be the skull of a Neanderthal child. The association of the two different types in a single stratum is explained as due to an Aurignacian burial. The stratigraphy of the cave shows no trace of occupation after Aurignacian. The industry is Aurignacian overlying Mousterian. Associated with the Aurignacian implements were the bones, intentionally broken, of *Equus*, *Bos* and *Rangifer*, while in the stratum below, where an Aurignacian industry overlies Mousterian, the human remains were associated with *Elephas primigenius*, *Rhinoceros tichorhinus*, *Hyaena spelaea*, *Ursus spelaeus*, etc., belonging to Middle or Upper Quaternary. The age of the Neanderthal child of Engis, as indicated by the dentition, is probably less than seven years. None of the milk teeth had fallen. The molars had not yet erupted. The median permanent incisors are enormous and their pulp cavity much larger than in *Homo sapiens*. The enamel of the molars shows the characteristic creases found in the child's skull of Gibraltar and of La Quina, as well as in the anthropoids and *Sinanthropus*. The Engis child shows an acceleration in the development of the cranial skeleton, which is still sometimes found in the inferior races, and is characteristic of the great apes; and it also shows the characteristic position of the foramen in which Neanderthal man approaches the apes. The temporal bone, and in particular the tympanum, shows primitive characters which disappear in the adult, but are found in the human fœtus, in *Sinanthropus* and to some degree in certain species of apes.

Archæological Excavations in Moravia

SOME further important archæological discoveries have just been made, according to an announcement in the Central European Press, at Věstonice in the valley of the Dyje, Moravia, near the place where the 20,000 years old 'Věstonice Venus' was unearthed some six years ago. Large numbers of stone and bone implements, some of them of a unique type, have been unearthed. One of the objects is a spear, thirteen inches long, carved out of a horn from a diluvial stag in excellent condition, and, like the five-inch female figure of the Moravian mammoth hunters, testifies to the skill of the artists of that period. Handsome pendants and carved ornaments of mammoth bone, crystal spheres and implements chipped out of quartz, and a stone borer unique for the Moravian diluvium are among other interesting finds.

Swallows in Britain

FOR two years an inquiry covering many aspects of the life of the swallow has been conducted in Britain under the auspices of the British Trust for Ornithology. The results of the 1935 inquiry are summarized in *British Birds* (30, 98, Sept. 1936) by A. W. Boyd. It would appear that swallows in the Lowlands of Scotland and north England lay larger clutches and rear larger broods than birds breeding in the southern part of England, and the suggestion is made that the fact may be associated with longer hours of daylight in northern latitudes. But we surmise that amount of food must be involved, and that no increase of daylight in the absence of increase of food would affect the clutches. How many eggs do swallows lay in the extreme north of their breeding range? Heavier rainfall cannot be shown to have any adverse effect upon size of clutches. The average brood for the whole country is just over four; the normal clutch is five, but six eggs, usually found in the northern counties, are not infrequent. The density of swallows varies enormously, from 40 pairs to 1,000 acres in well-populated rural districts of Norfolk and Anglesey where nesting-sites are common; to between 20 and 33 pairs in the cattle-raising districts of western England and Wales; and low numbers, 2 to 6 pairs, in industrial areas, in a large area of the Lake District, and on the downs of Sussex and moors of Suffolk.

The Migrations of Birds

A VALUABLE summary of the voluminous and scattered literature upon the migratory movements of birds in 1926–35 is given by Dr. A. Landsborough Thomson in the *Ibis* (p. 472, July 1936). The report classifies and groups the findings of field observations and experiments, and shows in what respects old theories must be modified to meet new knowledge. The portion which ought to make the greatest appeal to ornithologists in general is that dealing with recent experiments devised to elucidate the fundamental problems of migration, its purposes and origin, the stimuli which set migrants on their journeys, and the forces which guide them; for experimental evidence has greatly narrowed down some of these problems in recent years.

American Land and Freshwater Isopods

A MOST useful monograph recently published is Willard G. Van Name's "The American Land and Fresh-Water Isopod Crustacea" (*Bull. Amer. Mus. Nat. Hist.*, 71; 1936). The author gives a description and figure, or figures, of all species known from North and South America and the neighbouring islands, and also describes many new species. The introductory remarks on the general characters and relationships of the group are clear and simply written, enabling a beginner to benefit by them, and yet the whole is a handbook for any specialist to use. There are 254 land isopods, very nearly 75 per cent of which are found in that part of America which lies within or close to the tropics, including the West Indies as well as the continental areas, and there are 49 freshwater species, 17 being tropical. There are no freshwater isopods known from Bermuda, Galapagos and Juan Fernandez Islands, and the few land forms are largely species from the Old World and littoral forms, a few species being peculiar to the islands. It is satisfactory that the genus *Ligia* is used here instead of *Ligydia*, and we heartily agree that to upset and abandon so well established a genus as *Ligia* Fabricius on such insufficient grounds is unjustifiable.

Fasciation in Plants

A COMMUNICATION has been received from Mr. C. J. Bond, of Fernshaw, Springfield Road, Leicester, which raises the question as to whether the hæmagglutinating substance present in the watery extract of the seeds of the runner bean, *Phaseolus multiflorus*, but absent from the seeds of the broad bean, *Vicia Faba*, may have any connexion with a fasciation he has observed to occur when the axillary shoots grow out, after the amputation of plumule and cotyledon, in the runner bean but not in the broad bean. Mr. Bond finds that the hæmagglutinating substance is present in the cotyledons of the seed of the runner bean but not in the cotyledons of the seedling, which are 'exhausted' by the demands of the growing seedling. It remains for further work, however, to show whether this substance is causally connected with the fasciation of the axillary shoots forced into vigorous growth after amputation of the plumule and one or both cotyledons.

Mosses of Fiji

THE strategic position of the Fiji Islands in connexion with the geographical distribution of flowering plants applies equally to the mosses. A strong thrust of typical south-eastern Malaysian species indicates a migratory current through the region. Mr. Edwin B. Bartram has recently dealt with two hundred numbers collected by Dr. A. C. Smith in 1933–34 on outlying islands, previously unvisited by a botanist, and difficult of access, and with a few small specimens separated from J. W. Gillespie's plants in the Herbarium of Bernice P. Bishop Museum ("Contribution to the Mosses of Fiji", by Edwin B. Bartram: *Bernice P. Bishop Museum Occasional Papers*, 11, No. 20, March 20, 1936). Additional records of nineteen established species and twelve new species increase the total of known mosses from Fiji to approximately two hundred and thirty-five.

Ecology of Alkaline Lakes of the Rift Valley

IN the final report on the work of the Percy Sladen Expedition to some of the Rift Valley Lakes in Kenya in 1929, Penelope M. Jenkin deals with the general ecology of the alkaline lakes in particular (*Ann. Mag. Nat. Hist.*, S. 10, 18, 133, July and Aug. 1936). The number of species in the alkaline lakes is small: 17 species of algæ, 11 of invertebrates, no fish or amphibia, but a large number of flamingos which come to feed upon the blue-green algæ. The paucity of the inhabitants is the more remarkable because in a neighbouring fresh-water lake, Naivasha, there were 89 species of algæ and 70 of invertebrates. The peculiar conditions of the alkaline environment apparently make for variation, since ten of the seventeen species of algæ and nine of the invertebrates were new to science. A characteristic feature of the alkaline lakes is a 'water-bloom' due to the seasonal rapid multiplication of the blue-green alga, *Arthrospira platensis*.

Paulin Aneroids

AN account of the aneroids constructed on the Paulin System appeared in NATURE of February 23, 1929 (p. 298). Since that time the instruments have been improved and their use has been extended. Their manufacture is now in the hands of a well-known Swedish firm, Telephonaktiebolaget L. M. Ericsson, of Stockholm, and their distribution in the United Kingdom is in the hands of C. E. Johansson, Ltd., 12 Queen's Road, Coventry. The null reading principle is retained. The total range of movement of the diaphragm of these aneroids is still restricted by stops to a maximum of 1/40 mm. The diaphragm is kept expanded by a spiral spring the tension of which is altered by a micrometer screw. The spring is set until the diaphragm is in a certain normal position which can be observed on a small scale marked with a zero line, and the movements of a pointer attached to the micrometer screw are read on a large circular scale graduated to give the atmospheric pressure, the variations of which are compensated for by the variations of the tension of the spiral spring effected by hand. It is claimed that the errors of hysteresis, which constitute the worst defect of the ordinary aneroid, are practically eliminated by this null method, and that great sensitivity is attained without the production of frictional errors of the size of those introduced when the movements of a diaphragm are greatly magnified by a system of levers. The latest catalogue does not say how the problem of correcting this mechanism for changes of temperature has been solved, but states that such errors have been greatly reduced, and that the temperature coefficient is not only very low but also much more constant over the ordinary range of temperature than in the ordinary type of aneroid.

Cloud Chamber Observations of Cosmic Rays

C. D. ANDERSON and S. H. Neddermeyer (*Phys. Rev.*, 50, 263; 1936) have taken a large number of Wilson cloud chamber photographs of cosmic ray phenomena on Pike's Peak at an elevation of 4,300 metres. The chamber was set off automatically by the cosmic rays through the usual coincidence counter control, and a magnetic field of 8,000 gauss was maintained by a solenoid. The tracks obtained are similar to those at ground level, but 'showers' are more frequent in relation to the general cosmic radiation. It seems furthermore that showers containing a large number of tracks increase more rapidly with altitude than smaller showers. Some measurements of the energy loss of fast particles going through lead plates in the chamber were made. A certain number of strongly ionized tracks were found, corresponding probably to 'heavy' particles and most probably to protons. They appear to be ejected in all directions, and to be secondary rays produced by nuclear disintegrations. The high energies of these particles show that they must be produced by the cosmic rays. A search at sea-level for protons made with a special ionization chamber by C. G. and D. D. Montgomery, W. E. Ramsey and W. F. G. Swann (*Phys. Rev.*, 50, 403) showed that these did not exceed 5 per cent of the total rays.

Separation of Gaseous Isotopes by Diffusion

THE automatic multiple diffusion apparatus invented some years ago by G. Hertz has been studied in considerable detail by D. E. Wooldridge and W. R. Smythe (*Phys. Rev.*, 50, 233; 1936). It consists of porous diffusion tubes with diffusion pumps arranged to collect the gas as it diffuses through and to return it to the appropriate part of the fractionation system. In order to examine the behaviour of the apparatus, it was used to separate mixtures of nitrogen and carbon dioxide. The separation obtained with an apparatus of twenty-four elements agreed well with theory. An apparatus with thirty-four elements was used to concentrate ^{13}C in methane and ^{15}N in nitrogen gas.

A Middle-Babylonian Chemical Text

C. J. GADD and R. Campbell Thompson (*Iraq*, 2 (1), 87; 1936) describe a cuneiform tablet from Tall 'Umar (Seleucia) of the reign of Gulkishar, not later than the seventeenth century B.C., written in an intentionally obscure way by a supposed member of a guild of glassmakers. This is much earlier than the well-known Assyrian chemical texts from Nineveh (seventh century B.C.), and contains the oldest known record of actual formulæ for making glazes. The cuneiform text, its transliteration, and an attempted translation are given. Two glazes, called "lead copper" and "Assyrian copper", are composed of specified amounts of *zukû*-glass, lead, copper, lime and *mil'u* (translated 'saltpetre'). The clay for the body of a pot is then steeped for three days in a mixture of vinegar and copper, which gives a 'bloom' (verdigris). The pot is fired, and then a melted mixture of the two glazes, together with some of a similar composition, is made. A sacrifice to the "incomplete dead" (perhaps the embryo) is made, the glaze is applied and the pot is fired twice, with an addition to the glaze of a composition as before but without lime.

Modern Treatment of Burns

IN the first-aid treatment of severe burns and scalds time is an essential factor, and the treatment applied in the early stages determines to a large extent the subsequent course of healing and recovery. The former almost universal first-aid treatment by the application of 'carron oil' seems likely to be superseded by the use of tannic acid. This agent, in the form of a 2·5–5 per cent solution, sprayed over the burnt area hourly for 8–12 hours, forms with the exudate a protective coagulum, allaying pain and preventing subsequent sepsis, which is so troublesome and dangerous. Various preparations of tannic acid have been compounded for immediate first-aid treatment, such as the "Tanna-Flavine Jelly" prepared by British Drug Houses, Ltd., Gresham Street, London, N.1. This is a non-oily preparation of tannic acid with the antiseptic dye 'acriflavine', which is put up ready for use in collapsible metal tubes suitable to form part of the equipment of first-aid outfits in works, schools and other institutions.

Electrically Driven Steering Gear

A PAPER read to the Institute of Marine Engineers by H. G. Leivesley on marine electrical installations in service is reprinted in the *Metropolitan Vickers Gazette* for August. Steam steering gear has the advantage of low initial cost over steering gear electrically driven. The steam consumption is high and is constantly taking place even when the helm is at zero. This is due to lag in the transmission scheme and to the failure of the valves to close fully. The lack of synchronism between the helm position and the steering engine and consequently the actual position of the rudder is improved by the provision of a rudder indicator. This device operated from the rudder post gives a reading on a large-scale instrument in the wheelhouse. This affords the helmsman a definite indication of the rudder's position. As rudder angle means steam consumption, this affords some means of correction, and the consumption of the steering engine can be reduced. In long steam lines the losses due to condensation still continue. Water rates taken on a general cargo ship of 3,000 h.p. showed that the steering engine was responsible for seven per cent of the total fuel consumption. In motor ships and passenger liners, steering gear of the electro-hydraulic type is now standard practice because of the overall economy and convenience. In large ships the steering equipment is run continuously in one direction and at almost the same speed throughout the load range. In this case the motor is not subjected to any heavy stresses consequent upon starting, putting on a sudden load or reversal. For cross-channel steamers the horse power of the steering gear is 10, for a cargo ship 15 and for a liner 40. Curves obtained by tests show the ability of the modern steering motor to deal with sudden and heavy overloads when putting the helm hard over from varying degrees of rudder angle under full power steaming conditions.

Science and the Glasshouse Industry

IN connexion with the Blackpool meeting of the British Association, Dr. W. F. Bewley delivered a public lecture on "Science and the Glasshouse Industry" at Blackpool South on September 11. Dr. Bewley prefaced his remarks by directing attention to the importance of protected crops in any scheme of food production which might become necessary if Great Britain should ever be faced with another war, and argued that new land should be broken with the plough and brought into the high state of fertility which is essential for the successful cultivation of vegetables. He also stressed the value of such crops in the diet of the people.

To form an accurate opinion of the way in which science has helped the glasshouse industry to overcome the pests and diseases which once threatened its very existence, and the way in which it has directed progress, it is necessary to consider the position prior to 1914, when organized research became possible through the establishment of the Cheshunt Research Station.

Dr. Bewley described the serious damage once caused by the tomato moth caterpillar *Polia oleracea* (£40,000 per annum in the Lea Valley alone), the white fly, *Trialeurodes vaporariorum* (£25,000 per annum), and the red spider mite, *Tetranychus telarius*. These pests were quickly controlled by measures devised at Cheshunt, and special note must be made of the importance of the chalcid parasite, *Encarsia formosa*, in controlling the white fly. Diseases such as 'damping off' and 'foot rot' caused by *Phytophthora* spp., which destroyed thousands of plants in glasshouses, *Verticillium* wilt of the tomato (*Verticillium albo-atrum*), tomato leaf mould (*Cladosporium fulvum*) and many other diseases of glasshouse plants, which once extracted an enormous annual toll, were also brought under control.

Dr. Bewley directed attention to the importance of using a clean water supply in connexion with glasshouse plants and described the work done at Cheshunt on this problem.

The 'damping off' work was the means of discovering a soil drench (Cheshunt compound) which has since been applied on a large scale for the purpose of destroying certain fungi in the soil without injuring the growing plant. A large amount of work has also been done in connexion with virus diseases, which have attracted much attention during the past ten years. Virus diseases of the tomato were described in detail, and methods for identification, prevention and control were discussed. The importance of using virus-free seeds was emphasized. It was stated that scientific research has been pursued so effectively that it is now possible to control most of the serious pests and diseases of glasshouse plants.

Passing to the question of fungicides and insecticides, Dr. Bewley paid tribute to the work of many investigators in research institutes, universities and chemical firms, whose labours have provided the vegetable growers with new sprays of greater effectiveness. He mentioned the importance of the new sulphonated oil wetting agents and the work which is being done with regard to the use of insecticidal and fungicidal compounds carried in emulsified oils.

Soil sterilization has played an important part in glasshouse work, and the processes of chemical and heat sterilization were described. Sterilization by heat is the most effective and widely used, because it destroys a wide range of organisms, whereas chemical compounds are specific in action and it is difficult to obtain satisfactory penetration of the soil in practice. The latest method of steam sterilization, by means of the 'Hoddesdon' pipe system, was described.

Work at Cheshunt has included the breeding and selection of better varieties of tomatoes and lettuce, and of tomatoes resistant to *Cladosporium fulvum*. The tomato variety E.S.1 was distributed ten years ago and is widely used, for it yields a heavy crop of good quality fruit. The work on resistant varieties has been in progress for nine years, and it now seems that the goal is in sight, for good types have been grown this year which possess a high degree of resistance to leaf mould.

The lettuce Cheshunt Early Giant is one of the triumphs of the Station. It fills a long-felt want, for it can be grown in heated glasshouses from September until March and produces large well-hearted lettuce, even at Christmas. It has provided the English growers with a splendid opportunity for beating their foreign competitors, by providing fresh well-hearted lettuce during the autumn and winter.

In glasshouse work the physical condition of the soil is of great importance. Clean straw placed in the soil with the haulms vertical has proved beneficial, as has also the use of peat either mixed with the top soil or applied as a rooting medium to the surface of the soil during the summer.

Dr. Bewley also discussed the latest methods for warming the soil by circulating hot water in pipes buried two feet below the surface. This is a new development which will no doubt become general practice in the future. Soil warming increases the rate of root production, provides large clean root systems and heavy crops. It also increases the weight of crop picked during the first few months.

The workers at Cheshunt have also investigated the use of artificial light during the propagation stages. Useful results have been obtained with cucumbers but not with tomatoes. This application of light is being held up because a suitable source of light has yet to be found. This is a task for the engineers. Engineering science has helped the glasshouse industry in the question of heating, and Dr. Bewley discussed the use of oil firing, automatic underfed stokers, gravity boilers and the steam-cum-water system.

Great importance is placed at Cheshunt upon the question of quality in vegetables of all kinds, and recently the question of tomato marketing packages was investigated. It was found that high temperatures cause the fruit to be disfigured by a yellow mottle known as 'high temperature mottle' and that bad ventilation causes softness. A new wooden box and perforated lining paper have been devised which allows the fruit to be adequately ventilated and kept in a cooler condition. It has been tested thoroughly during the past season and has given excellent results.

Chemistry and the Community

PROF. J. C. PHILIP'S presidential address to Section B (Chemistry) of the British Association delivered on September 10, on the function and training of the chemist in the service of the community, was of much more general interest than many recent addresses or discussions in this Section but was ill-rewarded by a rather smaller attendance than is usual at the presidential address to the Section. While this may be due in part to the counter-attraction of several other discussions of wide appeal taking place at the same time, the attendance at least suggests that chemists are a long way from being alive to the social implications of their work. Prof. Philip's address, however, received the strong support of the Section, and apart from its endorsement by subsequent speeches, the approval which met many of his pertinent remarks, such as those concerning the abuse of chemistry for destructive purposes and his criticism of premature specialization and the absurdity of a university department of chemistry finding it necessary to teach its students German, was plainly manifest. Sir Josiah Stamp, who was present, spoke briefly but emphatically in agreement with Prof. Philip's views.

Mr. M. P. Applebey, who followed, discussed the particular relations between industry and the profession of chemistry. In dealing with the scope of the chemist in industry, he quoted from the joint Report of the Chemical Societies of the North East Coast to the District Commissioner for the Special Areas, which forms such an admirable example of the way in which the profession can assist in handling social problems. Despite the wide scope of the chemist's work in industry his importance is not fully realized in some industries, and industry in Great Britain does not employ its due proportion of trained chemists. The chemist is most widely recognized as an analyst, but even for this purpose men of meagre qualifications are often employed, while some firms seem to consider that analytical work exhausts the possibilities of trained assistance from the chemist. As a plant manager, he has equally important functions, and chemical processes in operation require study by controllers who understand their scientific basis if efficiency and progress are to be secured. With the wider recognition of the value of technical knowledge in sales service, the chemist is finding another outlet for his services. Mr. Applebey also commented on the purchase of processes from abroad by firms in Great Britain, and pointed out that such a policy can never be a substitute for a research policy. In the absence of a research department, considerable sums may be spent on processes which prove to be impracticable, and even perfectly good processes may require much research to adapt them to the particular conditions or to acquire the intimate knowledge of their chemistry essential for successful operation.

Mr. Applebey went beyond Prof. Philip in his remarks about the place of the chemist in management, strongly maintaining that an education in chemistry or any of the exact sciences affords as good a mental training for management as some longer established courses of education. Turning to the relations between industry and chemical education, he urged that industry first requires strong and active schools of research engaged in the pursuit of knowledge and the discovery of principles from which applications may flow. Industry also looks to the schools of chemistry for a supply of suitably trained chemists to fill such posts as have been indicated. For this purpose a good honours degree is desirable, but the honours course in chemistry should be soundly based on fundamentals, giving a firm grasp of principles. Preferably the recruit should have had two or three years of advanced experimental work, usually research, designed to develop perseverance and resource as well as technique. An industrial basis in such research is neither necessary nor desirable. Industry's obligations to chemical education are best discharged by the subsidizing of research through research scholarships, by grants for special apparatus and chemicals and the support of fundamental work and of chemical publications, both directly and through encouraging its technical staff to become members of one or more societies and participate in their work.

Mr. C. J. T. Cronshaw prefaced his paper on "the Benign Gifts of Organic Chemistry" with an endorsement of Prof. Philip's remarks regarding the need for a broad scientific basis of training. The better chemists entering the organic chemical industry are acquainted with neighbouring and borderland sciences, the better fitted they are for their job. The chemist should understand the uses to which his products are put and be able to measure and assess such properties so as to be able to improve them. Early specialization is a danger; the study of science alone is liable to produce men lacking in general culture, with little literary ability and incapable of expressing themselves clearly. General culture, he suggested, may be improved by a study of history from the angle of the rise of industries in modern times under the influence of scientific developments. Finally, Mr. Cronshaw urged that the industrial recruit should cultivate the power of criticism and of co-operating with others in a team.

Mr. Cronshaw then gave a brilliant review of the development of industrial organic chemistry, commencing with the development of the dyestuffs industry and describing the myriad contributions of organic chemistry to our comfort and well-being to-day. The quest for colour, which in itself ministers to the need of many industries, has led the industrial organic chemist into many other fields, such as those of medicine in the provision of anæsthetics, and of remedies for sleeping sickness. As with dyestuffs, the tendency with progress is to advance from the general to the specific. The motor-car industry owes much to the organic chemist alike in the improvement of tyres, oil, petrol and the finishes used for it. Organic chemistry has given the textile industry two new fibres, and in its recent work on detergents and products for the control of pests and in the field of vitamins it is continuing to confer benefits on mankind.

Sir Henry Dale, in discussing the training of chemists for work in the fields of biochemistry and medicine, referred to the way in which chemistry in recent years has invaded the fields of functional biology and the sciences related to medicine. Even in the complex field of immunity, in recent years we have seen the beginning of exact description in terms of organic and physical chemistry. In the last few years a whole series of hormones has been isolated chemically and several synthesized. Four or five vitamins have been identified chemically and at least three synthesized. Sex hormones, one vitamin, carcinogenic substances and heart tonics have been chemically related to the typically inert sterols. Already new substances have been synthesized which promise to give control over some of the most deadly infections of man, especially in the tropics. The whole orientation of therapeutics is being shifted from the effects to the causes of disease. Sir Henry Dale suggested that the greatest service of chemistry to the community lies in this new and increasing domination of biological and medical research by chemical methods and ideas. In urging the necessity for co-operation between the chemist and those trained primarily in biology and the medical sciences, he protested strongly against the neglect in Great Britain of the study of tropical diseases. While we control more of the tropics than any other country in the world, we have done comparatively little in attacking the problems of tropical disease. It is unlikely that we shall be able to justify permanently the possession of large sections of the globe, and depend on the efforts of other nations to make them habitable.

The Mediterranean Littoral

THE Consiglio Nazionale delle Ricerche has undertaken, through the agency of the National Committee for Geography in conjunction with the Institute of General Geography of the University of Pisa, an inquiry into recent conditions affecting sandy beaches along the Italian littoral, and in this connexion is publishing a series of monographs dealing with the coastline in ten regional sections, each of which is to form the subject of a separate volume. In this way, reviving the studies of eminent physiographers of the past, it is intended to present a chain of facts which will serve for a systematic research into the regimen of Italian beaches and so foster the advancement of scientific geography, at the same time aiding in the development of maritime engineering.

The opening volume of the series, forming an introduction to the whole subject, has been prepared by Signor Agatino D'Arrigo*, an engineer of acknowledged competence and merit, who has received the distinction of the award of a premium from the Royal Academy of Italy for his publications on coastline phenomena. He has produced an excellent historical review of the subject, giving an account of the earlier investigations of Italian observers from Leonardo da Vinci, Montanari, Marsili and Paleocapa to Cialdi and Cornaglia, including at the same time appropriate references to the facts recorded by writers of other nationalities. The first part of the volume is taken up with this disquisition, and is followed by certain deductions of a general order to which limitations of space do not permit reference in detail.

The second part consists of a series of comparative morpholithological studies of the regimen of various parts of the Mediterranean littoral, including the Nile Delta, the Delta of the Po and the adjacent Venetian region, the Delta of the Rhone, the Delta of the Tiber, the Bay of Taormina, the Algerian Littoral and the Argentarian Promontory, with a final chapter embodying the conclusions of the author.

The investigations are obviously spread over a wide field and while they serve as an admirable introduction to a further and more complete survey, their immediate value is perhaps best assessed, as stated by Prof. Toniolo in his preface to the volume, as a general confirmation of the hypothesis already advanced of the probable reversibility of the cycle of evolution of the Mediterranean littoral. For physiographers of other nationalities, the book contains a great deal of serviceable information, with useful references to the work of Italian investigators. The treatise, in fact, is commendably documented, and there is an excellent set of coloured charts showing coastline changes at various dates. B. C.

Educational Topics and Events

WILD-BARFIELD ELECTRIC FURNACES, LTD., Elecfurn Works, North Road, Holloway, London, N.7, have prepared a series of lantern slides illustrating many types of electric furnaces for heat-treatment, together with notes regarding the various slides. These form the basis of a paper on such equipment, and sets and lecture are available for societies, technical schools or other interested bodies.

FORMAL education for marriage is advocated by Paul H. Landis of the State College of Washington in an article on "Control of the Romantic Impulse through Education" published in *School and Society* of August 15. The mounting divorce rate in the United States, now higher than in any other country, is, he suggests, attributable in some measure to the frequency of romantic marriages, and of this the chief cause is the mobility characteristic of contemporary American life, especially in the West, where the divorce rate is highest. "In most fields now we believe in giving experience vicariously through books and the school curriculum, yet in the field of marriage and the family we let youth learn by experience." We need courses in high school and college in eugenics and the essentials of happy family life, to set up new barriers to the free exercise of the romantic urge.

THE Education Act 1936 throws upon local education committees a heavy addition to their responsibilities. In persistently agitating for the raising of the obligatory school age, for which the new Act provides, they have, as an editorial in their official organ, *Education*, of September 4, points out, created for themselves a vast moral obligation. The issues involved in adjudicating upon applications for exemption closely concern the well-being of the community: the health and physical condition of the child; the 'beneficial' nature of the proposed employment, including its prospective benefit; the opportunities to be afforded of free education; the time available for recreation; and the case of each individual child will call for careful consideration. The grant of an employment certificate in respect of an exempted child is clearly intended to be a deliberate judicial act, not the routine application of a rough and ready test. An incidental advantage of this procedure will be that members of the committees will be constantly face to face with the question—what is the content of this final year of compulsory schooling and what is its probable value in any particular case? It is, the article points out, in this connexion, that loyal and willing co-operation between the Board of Education, local authorities and teachers will be specially desirable. A series of articles by Dr. Percival Sharp, secretary of the Association of Education Committees, on the problems presented by the administration of the new Act, is promised.

THE 'brain trust' in American politics is symptomatic of that pronounced swing towards the social sciences which has been one of the most noticeable features of university life in the United States in recent years. Commenting on this movement, the president of Yale University in an Alumni Day address urged the frank and definite recognition by universities of the "preponderant importance for our day and for the immediate future of the crucial problems of the industrial and economic order and of the individual human life in all its physical, social and spiritual aspects". Failing such recognition and energetic fulfilment of the universities' correlative obligations to the social order, they may have to face "the destruction of all that we and our predecessors have given our lives to create". But the 'brain trust', in so far as it involves the exploitation of university faculties by Government departments, is obviously liable to abuse, and a public protest has, according to *School and Society* of July 25, been made by Mr. Walter Lippmann and eight other prominent alumni of Harvard against the consequential neglect by professors of their academic duties. In Great Britain, on the other hand, one doubts whether Government departments make sufficient use of the brains of university staffs and advanced students. In the Ministry of Labour's report for 1935, for example, there is no evidence of contact between the Ministry and university departments concerned with cognate matters, although these doubtless study the masses of statistics provided by the Ministry.

THE president of Columbia University, New York, Dr. Nicholas Murray Butler, in his recent "Commencement Day" address on "The Decline and Fall of Morals", quoted Thomas Jefferson's prophecy that the cult of the "almighty dollar" would lead to heavier and heavier shackling of the people's freedom "till our rights shall revive or expire in a convulsion" —an alternative which is, Dr. Butler declared, the one dominant question before the world to-day. With this question is also bound up the fate of morals, for the destruction of liberty would make morals impossible. He referred to the German people's once powerful influence in the intellectual and economic life of the world, forfeited for the time being under a self-confident tyranny that boasts (Dr. Goebbels, on March 19) "we do not have to appeal to the people, we have the army, the police, the wireless, the press, the Nazi organization". He noted the utter disregard by Japan and Italy of moral obligation and their recourse to mass murder, and the strange mutation of Mussolini's principles since 1913, when he rebuked his countrymen for the "stupid orgy . . . in which the Italian press is now letting itself go with mad exaltation. Strong peoples have some sense of measure. Italy, rationalist and militarist, shows that it lacks this sense . . . a miserable war of conquest (the conquest of Tripoli) is acclaimed as if it were a Roman triumph." Another university president, Dr. Sproul of the University of California, speaking on June 30 on "America's Answer to Youth's Appeal", similarly stressed the preponderant importance for our day of safeguarding "freedom and tolerance, respect for the individual, regard for the rights of minorities. . . ."

Science News a Century Ago

J. D. Forbes and Auguste de la Rive

THE enthusiasm shown at the Bristol meeting of the British Association in the experiments of Andrew Crosse, referred to in NATURE last week, was not shared by J. D. Forbes, who shortly after returning from Bristol, on September 26, 1836, wrote to Auguste de la Rive: "The subject of Mr. Cross is, I confess, rather a disagreeable one to me. You will readily enough conceive how much people more conversant with geology than electricity must have been struck by hearing most eloquently expounded a series of experimental discoveries, for they were perfectly original to Mr. Cross, silently prosecuted for many years by a retired country gentleman in Somersetshire, and only elicited by chance in the course of discussion. From the first moment that the matter was mentioned to me, and on every succeeding occasion, I really believe not less than fifty times, I have patiently vindicated the claims of Becquerel, which only require to be mentioned to be acknowledged. I own I felt somewhat indignant on the subject, because having seen Becquerel's magnificent preparations and conversed at great length with him on the subject, I had been led at various times, publicly and privately, for several years, to draw the attention of geologists to one of the very best things ever done for their science. . . ."

Medical Museum at King's College, London

ON September 30, 1836, *The Times* said: "The Society of Apothecaries has lately enriched the various collections in the medical school [of King's College] by the presentation of a large and beautiful series of specimens of the materia medica, being duplicates of those selected from their own collections at Apothecaries-hall. As much care is required in choosing the purest and best specimens, many of which it requires time to procure, it is not expected the collection will be quite complete for many months. A new room has been opened in the college for their now extensive museum of materia medica. The dormitories for the students, fully furnished, and abundantly ventilated, a new medical reading room, as well as dining-hall or refectory, to be opened early in October, are among the newest improvements in the college."

Sturgeon's *Annals of Electricity*

IN October 1836 appeared the first number of the periodical "The Annals of Electricity, Magnetism, and Chemistry and Guardian of Experimental Science, conducted by William Sturgeon, Lecturer on Experimental Philosophy at the Honorable East India Company's Seminary, Addiscombe, etc., and assisted by gentlemen eminent in these departments of philosophy". The greater part of the number appears to have been written by Sturgeon himself. There were articles on the galvanometer, electro-chemical action exercised by simple metals in fluids, electro-pulsation and electro-momentum, a letter from Sturgeon to Faraday and a description of an electro-magnetic engine for turning machinery.

Sturgeon was undoubtedly one of the most industrious men of science of his day. He was born in a village near Kirkby Lonsdale, Lancashire, in 1783, and at thirteen years of age he was placed under a shoemaker who starved and ill-used him; at nineteen he entered the militia, at twenty-one became a private in the Royal Artillery and at thirty-seven left the army with a pension of a shilling a day. He had meanwhile taught himself mathematics, Greek and Latin, and begun his electrical experiments. On leaving the army he set up as a bootmaker at 8 Artillery Place, Woolwich. In 1823 he began contributing to the *Philosophical Magazine*, and in the following year, mainly through Olinthus Gregory, S. H. Christie and Peter Barlow, was appointed to the lectureship at Addiscombe. He was also connected with the Adelaide Gallery of Practical Science in Adelaide Street, London, and in 1840 removed to Manchester to superintend the Royal Victoria Gallery of Practical Science, an institution which, however, had but a short life. His writings were very numerous and to him we owe the construction of the first soft-iron electro-magnet. In his later days he felt the pinch of poverty, and a year before his death in 1850, he was granted a Civil List Pension of £50 a year.

Darwin's Reflections on Travel

On October 2, 1836, H.M.S. *Beagle* arrived at Falmouth after a voyage which had taken her round the world and had lasted nearly five years. In concluding his "Journal of Researches", Darwin gave a short retrospect of "the advantages and disadvantages, the pains and pleasures, of our circumnavigation of the world". In concluding this retrospect, he said: "it appears to me that nothing can be more improving to a young naturalist, than a journey in distant countries. It both sharpens, and partly allays that want and craving, which, as Sir J. Herschel remarks, a man experiences although every corporeal sense be fully satisfied. The excitement from the novelty of objects, and the chance of success, stimulate him to increased activity. Moreover, as a number of isolated facts soon become uninteresting, the habit of comparison leads to generalisation. On the other hand, as the traveller stays but a short time in each place, his descriptions must generally consist of mere sketches, instead of detailed observations. Hence arises, as I have found to my cost, a constant tendency to fill up the wide gaps of knowledge, by inaccurate and superficial hypotheses.

"But I have too deeply enjoyed the voyage, not to recommend any naturalist, although he must not expect to be so fortunate in his companions as I have been, to take all chances, and to start, on travels by land if possible, if otherwise on a long voyage. He may feel assured he will meet with no difficulties or dangers, excepting in rare cases, nearly so bad as he beforehand anticipates. In a moral point of view, the effect ought to be, to teach him good-humoured patience, freedom from selfishness, the habit of acting for himself, and of making the best of every occurrence. In short, he ought to partake of the characteristic qualities of most sailors. . ."

Societies and Academies

Paris

Academy of Sciences, August 3 (*C.R.*, 203, 353–392).

Emil J. Gumbel: The extreme periods between radioactive emissions. Comparison of theory and experiment for polonium. The good agreement between the frequencies found and the probabilities proves that the extreme periods between the radioactive emissions follow the theory of the greatest value.

S. Lechnitski: Some problems of elasticity of anisotropic bodies.

Kyrille Popoff: The solution of the differential equations of the pendular movement of a projectile.

Daniel Chalonge: A remarkable variation in the spectrum of γ-Cassiopeia. An appreciable increase in the brightness of this star was noted on the night of July 25–26 last: spectroscopic observations made on July 30–31 and August 1–2 showed a change in the spectrum mainly due to a large increase in the emission of Balmer lines.

René Rivault: Experimental researches on the propagation of short electric television waves ($\lambda = 41 \cdot 5$ metres, $\lambda' = 74$ metres).

Maurice Dodé: The thermochemistry of the nitrites of the alkalis and alkaline earths.

Basile Fedoroff: The conductivity of the double sulphates of the magnesium series in aqueous solution. Eight double sulphates have been studied. Except at very low concentrations, the double salt is always less dissociated than the simple salts.

Clément Courty: The increase of the magnetism of ferric oxide by ignition in the presence of ash-free filter paper.

Gabriel Bertrand: Observations on the preceding communication concerning the discovery of iron in plant ash.

Georges Jouravsky: The optical properties, densities and degree of corrosion of the alumino-magnesium titanomagnetites.

Henri Ringard and André Duparque: The microscopic characters of Courrières coals.

Fernand Jacquet: The middle Eocene with Nummulites of Senegal.

Yves Milon: The fossil *yardangs* of Saint-Pierre-la-Cour (Mayenne).

Conrad Kilian and Théodore Monod: The discovery in the western Sahara of fossil micro-organisms forming an indicator as regards age and marine nature of the Koundeloungou (Congo) series.

Lucien Cayeux: Remarks on the preceding note.

Jean Dufay: The Huggins bands in the spectrum of the blue sky and the temperature of atmospheric ozone.

Paul Budker: The destruction and fall of the mandibular teeth in *Squalus*.

Jean Jacques Bounhiol: Metamorphosis after ablation of the *corpora allata* in the silkworm (*Bombyx mori*).

Stig Veibel and Franciska Eriksen: The influence of aglucone on the velocity of hydrolysis of the β-glucosides by emulsine.

August 10 (*C.R.*, 203, 393–416).

Lucien Daniel: Acquired heredity in bulb producing leek.

David Belorizky: Some peculiarities of Nova Lacertæ, 1936. The radiation of this star is monochromatic and almost entirely concentrated in $H\alpha$ radiation.

MLLE. YVETTE CAUCHOIS: Observation and measurements of the $L\alpha$ satellites for the elements 68, 70 and 71.

HORIA HULUBEI: Observation and measurement of the L spectrum of radium (88) I.

JOSEPH CATHALA and JEAN CLUZEL: The spectrophotometric study of the hydrolysis of ferric salts.

ETIENNE VASSY: Spectrographic method for the study of the thermal decomposition of ozone.

LOUIS FAUCOUNAU: A new method for the preparation of catalysts. The Raney method of preparing active nickel by attacking a nickel-aluminium alloy with alkali has been extended to alloys of copper and cobalt.

HENRI COUPIN: The germination of pollen grains.

LOUIS GALLIEN and MARC DE LARAMBERGUE: Cycle and sexual dimorphism of *Lacuna pallidula*.

CHARLES DHÉRÉ and OSCAR BIERMACHER: The living geranium leaf emits a fluorescence radiation which extends in the infra-red to λ 830 mμ.

RENÉ WOLF, MAURICE RANGIER and MLLE. ANDRÉE BOURQUARD: The relations existing between the magnesium of muscle and chronaxy.

August 18 (*C.R.*, 203, 417–444).

VITO VOLTERRA: The principle of least action in biology.

HERMAN AUERBACH: The analytical representation of Lie groups.

CAÏUS JACOB: A gaseous jet.

JULIEN KRAVTCHENKO: The problems of conformal representation of Helmholtz.

GINO ARRIGHI: The movements of a deformable body associated with general electro-magnetic fields.

NY TSI-ZÉ and WENG WEN-PO: The absorption spectrum of potassium. In addition to the lines or bands already described by H. Kuhn and by Datta and Chakravarty, new lines or bands have been found, and these have been empirically classified in series.

HENRI LONGCHAMBON and GEORGES MIGEON: The sepiolites. Results of a physical and chemical examination of three specimens of sepiolite from different sources and remarkable for their purity and crystal formation. Reasons are given for not adopting the theoretical interpretation recently proposed for sepiolites by J. de Lapparent.

ROBERT LAFFITTE: The Neocomian in Aurès (Algeria).

MLLE. MARIA LEJEUNE: A means of isolating the micro-fossils included in flints. Attack by gaseous hydrofluoric acid under the conditions specified gives better results than the aqueous acid proposed by other workers in the same field.

THEODOR SOLACOLU and DEMETRE CONSTANTINESCO: The action of β-indolylacetic acid on the development of seedlings.

M. SUREAU and P. GRANDADAM: The spectrophotometric estimation of α-œstrone and its derivatives.

Brussels

Royal Academy (*Bull. Classe Sci.*, 22, No. 6, 1936).

L. GODEAUX: A property of Green's first straight line of a surface.

P. GÉRARD: The significance of the terminal nerve according to observations made on *Polypterus Weeksi*.

C. PATERNOSTER: The advances and retardations of the transits of Mercury across the solar disk.

M. LINSMAN: The singularities of the elementary curves in finite geometry.

F. BACKES: R congruences.

T. H. J. LEPAGE: Geodesic fields of the calculus of variations.

C. PERELMAN: M. Gödel's antinomy.

J. PASTEELS: Analysis of the morphogenic movements of gastrulation in birds.

J. THOREAU: Crystalline calcic rocks of Kivu.

Moscow

Academy of Sciences (*C.R.*, 2, No. 5, 1936).

V. S. IGNATOVSKIJ: The Laplace transformation (2).

A. MITKEVITCH: Magnetic viscosity at different points of the magnetization curve.

A. A. GRUNBERG and J. L. MICHELS: Determination of iridium by potassium ferrocyanide titration.

P. PANJUTIN, L. HINDIN and O. VASILJEVA: An investigation of the autoxidation of carbohydrates. (1) A new method for the quantitative analysis of peroxide compounds.

A. EBERZIN and O. VJALOV: An ancient Euxinian terrace in the environs of Tuapse.

I. SMORODINCEV and K. BEBESHIN: The glycogen content of ascarids. Ascarids contains twelve times as much glycogen as the higher vertebrates, but only one tenth of their lipoids.

N. A. ŠČIBRIA: Hybrids between the Jerusalem artichoke (*Helianthus tuberosus* L.) and the sunflower (*Helianthus anmius* L.).

M. A. SIZOVA: Structural changes in chromosomes induced by irradiation of physiologically modified cells.

L. V. MICHAJLOVA: (1) Reaction of the drumhead cabbage to lowering of temperature. (2) Light regime requirements of tomatoes.

N. V. NASSONOV: Peculiarities and causes of the development of additional growths in Amphibia.

(*C.R.*, 2, No. 6, 1936).

I. NATANSON: Some remarks on the theorem of Stekloff-Severini.

G. KRUTKOW: Statically indefinite systems. The ultra-definite system.

B. FESENKOV: Absolute photometry of the solar corona. A method is discussed that makes it possible to eliminate completely the influence of the atmosphere.

N. SELJAKOV: Some remarks on α- and β-ice.

S. RYTOV: The diffraction of light by ultrasounds.

N. DOBROTIN: Absorption of neutrons in silver and cadmium.

V. M. KATUNSKIJ: (1) Intensity of geotropic reaction as a quantitative index of the content of growth-promoting substance. Intensity of geotropic curvatures of the coleoptiles of oats and the seedlings of castor-oil plants varies directly as the quantity of growth-promoting substance. (2) Growth-promoting substance and the formative action of light on vegetation in plants.

A. I. GREČUŠNIKOV: The physiology of the incubation period in rust infections.

G. D. ADLER: New data on the geological structure of the region of the Taimyr folding.

S. S. ELIZAROVA: The influence of hydrogen ion activity and of salinity on the eggs of *Engraulis encrasicholus* L. (anchovy). The limits of toleration to the pH concentration and the salinity of water differ in the Black Sea and the Azov Sea races of the anchovy.

Rome

Royal National Academy of the Lincei (*Atti*, 23, 161–249; 1936).

L. TONELLI : A fundamental proposition of mathematical analysis.

Leadership in Industry

THE wide attention now being given to training for management in industry is indicated by the discussion in Section F (Economics) of the British Association at the recent Blackpool meeting on the subject. This interest finds ample justification in a pregnant passage in the introduction to the recent annual report of the Industrial Health Research Board. The aim of the research work directed by the Board is to advance knowledge which may be used in the prevention of industrial misfits, the complex causes of which offer a wide field for investigation. While many factors enter into industrial fitness, advancing knowledge now offers the prospect of being able to lay down, though not rigidly, reasonable physical and mental standards for various occupations which should ensure for the operative entering industry a greater chance of maintaining good health, in the broadest sense of the word, during his working life.

Given, however, the best conditions of work and the most carefully selected body of employees, the final responsibility for the maintenance of health and contentment lies with the supervising staff. Accordingly, the greatest practical contribution of vocational tests to industry would be proof of their value in selecting such staff, from foremen to managers.

Scientific and technical matters are nevertheless not the only factors which increase the onus and responsibilities of management. The very demand of industry for alert, smart, active men, rather than men of brawn and muscle, brings fresh problems. While such men are more adaptable to the needs of modern industry, they are also more responsive to variations in their environment, more aggressive, quicker to make trouble, and to demand their rights, as well as more liable to forget their duties. Thus, as the Report points out, the modern manager of a labour force must be awake to the changes, physical and mental, which are taking place. He can no longer be a dictator or afford to be tactless.

Many of the investigations of the Industrial Health Research Board point to the conclusion that selection and training are especially needed for management. Corroborative evidence is provided by those passages of the recent report of H.M. Chief Inspector of Factories, in which reference is made to the opportunity of improvement in regard to the prevention of accidents in the education of the smaller and often non-associated employers.

The rising accident incidence rates among young workers affords another illustration of the extent to which scientific management has still to make its influence felt in industry. Similarly, the existence of gross overwork reported under hours of employment further indicates the many problems, such as the extension of the five-day week or the two-shift system, which call for scientific assistance both in the investigation and in the application of the results obtained.

If the importance of training for management is now fully realized in many quarters, the practical question of how such training is to be given is far from being solved, as the discussion at Blackpool referred to above clearly showed. Already academic courses of study are prolonged, and with their crowded time-tables tend to inculcate ready-made ideas without sufficient stress being laid upon a general background of fundamental natural laws, so that the average student readily loses his sense of individuality and the desire for original thought.

Merely to add a further course of lectures or classes to an overcrowded syllabus is unlikely to assist either the undergraduate or the young graduate to qualify for positions of responsibility in which clarity of judgment, a sense of values, and a knowledge of fundamental principles are among the first qualifications demanded.

In a valuable paper on accident prevention in industry, contributed to the Chemical Engineering Congress of the World Power Conference last July, Messrs. C. S. Robinson and H. R. Payne pointed out, for example, that most young technical men take up their first post in a works without having heard of accident prevention during their academic careers. Accordingly, in their keenness on their work they were liable, through inexperience, to endanger at first the safety traditions which their employers had been at pains to establish. Messrs. Robinson and Payne suggest accordingly that there is scope for the inclusion of accident principles in the training given to men destined for executive work in manufacturing industries.

This, of course, is not to suggest that training in accident prevention should be included in the curriculum of the university or technical college. It is rather a definite plea for closely thought out plans of training for all those entering the management or executive side of industry. The most important contribution which the university could make in this field is probably that of stripping its courses of study so that they stimulate originality and initiative. If, by divesting the syllabuses of much of their minutiæ, concentrating on the fundamental principles and leaving the student adequate time to think for himself, the university can supply recruits for industry who are characterized less by knowledge of unassimilated facts than by their grasp of principles, freshness of outlook and capacity for independent and critical thought, the most important first step in training for management will have been taken.

From such recruits, the training courses which many industries normally give will enable the more promising material to be sifted readily, while the general standard of assimilation and adjustment to the industry's requirements will be considerably raised. The question of further training and selection remains. Whether it is best to recruit a specially selected small group of individuals, providing them with special opportunities for acquiring experience, and promoting them rapidly as occasion offers to the higher administrative posts, is at least debatable. Frequently administrative ability, even of the highest order, develops only with experience, and accordingly it is of advantage to select staff for training for promotion to the highest positions of management not from the recruits entering the organization, but from those of a few years' service, whose record indicates sufficient promise.

For such promising employees some firms have used the Department of Business Administration at the London School of Economics as a kind of staff college, to give them a wider view of their work. The combination of training of this type, either external or, with the larger firms, internal, with the provision of special opportunities for acquiring experience for those whose ability has been further demonstrated in the training course, appears to offer special promise. There still remains, however, the necessity for the chief executives of the firm to devote their own time to the training of those destined to occupy the higher positions, and upon the quality and thoroughness of this training at present as much depends as on anything else.

The problem is, in fact, only partly that of recruiting the right type of material and providing the promising recruit with opportunities for sufficiently rapid promotion. It is also that of securing in the organization the tradition and atmosphere in which efficient management is possible. The highest possible type of recruit will prove largely ineffective if sound principles of business management are continually being violated in the organization, whether on the plea of privilege or expediency or anything else. Indifference to such matters undermines the efficiency of many firms to-day, and is a fatal obstacle in building for to-morrow an alert and efficient management competent to assess the many intricate factors involved, and to meet with knowledge and resource the ever-changing conditions of industry.

For this reason, the continued penetration of the professional spirit in the sphere of management, with its sense of social and professional responsibility and insistence on the linking of action to facts, is highly important. Even yet the lessons of the industrial revolution of the last century and more are largely unlearnt, and machinery tends to be our master and not our servant. Only as something of the scientific spirit takes charge, seeking to develop methods which eliminate the loss and inefficiency in the sphere of human or social relations and distribution, which have so far largely annulled or even outweighed the advantages which have come from the greater mechanical efficiency of power production and modern machinery, can we hope for the evolution of organization in which the machine is assimilated to human purposes.

The management of to-morrow cannot be content to think of efficiency in terms of mechanical and physical production alone. As Sir Josiah Stamp's presidential address at Blackpool suggests, it must take account of the direct and indirect consequences of mass production, monotony of work, nervous tension, leading to mechanization of mind and diminished creative power. In the narrowest sense, industrial efficiency cannot long be maintained at a high mechanical level if the social efficiency of the worker or consumer is low. Here, as much as in the field of distribution, are questions calling for close investigation if we are to evolve an industrial and social order in which the possibilities of higher standards of living now within our reach through power production are really utilized.

The fundamental demand, therefore, in industry as elsewhere, is for those who can bring to these problems of administration minds not only capable of grasping all the relevant facts and assessing values accurately, sympathetically and impartially, but also imaginatively alive to the future possibilities and free from the bondage of past traditions, whether in the economic or any other sphere. No less in the industrial than in the political world the creative mind is required, ready to adventure and experiment in a scientific spirit, unhampered by outworn conventions and traditional practices.

The Early Cultures of China

The Birth of China:
a Survey of the Formative Period of Chinese Civilization. By Herrlee Glessner Creel. Pp. 396+16 plates. (London: Jonathan Cape, Ltd., 1936.) 15s. net.

IT may seem remarkable that the Chinese with their passion for 'antiques' should have neglected their antiquities. The reason is not far to seek. Their intense interest in the past has been æsthetic and ethical, rather than archæological: chefs d'œuvre of art and literary sources, especially those of a philosophical cast or concerned with great personalities, exclusively absorbed their attention. In this we should be the last to blame them, for the history of study of the past in China runs closely parallel with that of similar studies in Britain. When once the researches of foreign scholars and students of geology, palæontology and anthropology had laid open other fields to their interest, the national pride in Chinese culture turned to research and exploration in the field. Since 1927, the National Institute of Research in History and Philology has pursued a policy of conservation and investigation, of which the remarkable results achieved recently in Chinese pre-history and history are presented in Dr. Creel's "The Birth of China".

In 1921 Dr. J. Gunnar Andersson, then attached to the Chinese Geological Survey, began an archæological exploration of northern China, which has now produced evidence of a neolithic culture on a large number of sites. One of the earliest and most interesting results to emerge was the existence there of a painted pottery of the highest quality, comparable to the painted pottery which had been found in western Asia, now known to be characteristic of a chalcolithic civilization and to extend from southern Russia to northern China. Further research, as yet, has by no means solved the problem of the relation of the Chinese neolithic culture with the West, nor has its internal development been fully demonstrated. The finds hitherto are regarded as late; but of these, what is apparently the earliest phase is characterized by a greyish coarse ware, which is followed by the culture of the painted pottery, presumably intrusive, but with a local centre of diffusion in north-west China. The painted pottery in its turn is followed by a 'black pottery culture', of which the first indication was found in Shantung in 1930 and 1931. Certain elements peculiar to China, and appearing more or less constantly throughout the neolithic, point to a certain continuity of culture, but the 'black pottery culture' introduces elements which are new to China, while its resemblances to later developments, notably in pottery technique, make it something of a connecting link between the earlier neolithic and the succeeding bronze age cultures.

Archæologists in Europe have had little opportunity of studying in detail the great development in the study of the civilization of the bronze age which has followed on the excavations of the National Institute of Research since 1928 at Anyang in northern Honan, North China. Indeed, the most remarkable of the results from this site, from which Dr. Creel derives a great part of his account of the civilization of the Shang dynasty in the work under notice, was obtained only in the excavations of the season 1934–35, which closed in June 1935. A great deal of this material is still unpublished, and detailed accounts of the previous excavations are available only in Chinese. Dr. Creel, who has inspected all the archæological sites of China and has made a close study of all the 'finds', has in preparation a detailed account and discussion of the evidence. In the meantime, his present summary is the only first-hand account of the material available, in part, even for those who may have access to the reports in Chinese.

Before systematic excavation was undertaken at Anyang by the Chinese authorities, at first in conjunction with the Freer Gallery of Art of Washington, D.C., it was not entirely unsuspected that the Chinese had attained a high degree of culture in the bronze age. Antiquities, mostly bronzes, for which a high antiquity was claimed, were of comparatively frequent occurrence in the 'curio' market; but in view of the complete lack of information as to the conditions of discovery, their archæological value, as evidence, was small. The authenticity of many was questioned, not least, perhaps, on account of the advanced character of their technique. When, however, a primitive form of Chinese script was recognized in 1899 in the engravings on ancient bones which, like the fossil tooth which led ultimately to the discovery of Peking man, were exposed for sale in a chemist's shop as "dragons' bones" to be used as medicine, it became apparent after prolonged study of these inscriptions that the bones had been used for divinatory purposes and were part of royal archives, in which were mentioned rulers of the Shang dynasty, dating in the Chinese reckoning from 1765 B.C. to 1122 B.C.

It thus became evident that a basis of archæological fact had been provided for part, at least, of Chinese records hitherto regarded outside Chinese circles as legendary. Fifteen thousand inscriptions in this early script, out of more than a hundred thousand known, have now been published in facsimile. They have afforded a wealth of information relating to early Chinese language, system of writing, religious belief and social organization, as well as on the history of the Shang dynasty and its relations with neighbouring peoples. A great part of the material evidence relating to this period, the choice pieces, in fact, was the loot from grave robberies at Anyang, and it was not until the excavations of 1934–35 that comparative material, accurately dated in the archæological sense, was available to establish its chronological position and evidential value. It is now known to go back not earlier than about the fourteenth century B.C.

In 1934 the Chinese authorities, following up the investigations of previous seasons, embarked on scientific excavation at Anyang on an extended scale, a large burial ground being examined. Some three hundred graves were opened, four of them being royal tombs of a vast size. The evidence obtained is of extraordinary importance and throws a flood of light on early Chinese material culture. Some scores of ritual bronze vessels were found, of which the technical excellence in metal work is nowhere surpassed. Of special importance to the anthropologist is the evidence of the physical characters of the early peoples of China, of which nothing was known previously. The skeletal remains of eleven hundred individuals were recovered, some of them in an excellent state of preservation. The greater part of this evidence was obtained from undisturbed ground and is, archæologically, accurately datable. One of the most surprising finds was an unsuspected art of sculpture in stone, of which a number of examples of high artistic merit were found.

In describing the civilization of China under the Shang dynasty, Dr. Creel has told only half his story. In 1122 B.C., the Shangs fell before the attacks of the Chou, a confederacy of peoples from the Wei valley to the west, of whom some had been described in Shang records previously as captives, slaves and tributaries. It is probable that in comparison with the highly civilized Shang people, they really merited the title of 'barbarian'; but apparently they readily adopted Shang culture, though, as the archæological evidence shows, with certain differences. If, however, they could then add little to the material culture of China, intellectual development and growth in social and political organization under the Chou dynasty was enormous. It was in this period that China attained what was to prove its highest development in literature and philosophy, and it was under the Chou that, after a period of feudalism, the Chinese were first consolidated in the sixth century B.C. into an empire, in which political administration and influence had been transferred to the scholarly class, and principles of government were laid down which not only endured, but also served to preserve Chinese culture continuously for more than two thousand years. It is the story of this period which Dr. Creel tells in the second half of his book, reinterpreting the evidence relating to this second great phase in the birth of China in relation to its archæology, in a reconstruction in which the Chinese so-called historical literature is regarded as an ideal picture rather than as a statement of fact.

The Parsons Steam Turbine

The Development of the Parsons Steam Turbine Part 1: Turbo-Generating Machinery; Part 2: Industrial Turbo-Machinery. By R. H. Parsons. Pp. viii + 420 + 96 plates. (London: Constable and Co., Ltd., 1936.) 42*s.* net.

IT has often been remarked that the invention and the development of the steam turbine have brought about a revolution in the generation of power both ashore and afloat. That revolution was entirely unforeseen, and when Sir Charles Parsons in 1884 took out his first patents and constructed the historic little turbo-generator now preserved in the Science Museum, South Kensington, there were few who recognized the significance of the invention and none but Parsons himself who dreamt of the changes it was destined to bring about. The ideas involved were so novel, the difficulties to be overcome so great and the problems to be solved so numerous that it can now create no surprise that only the inventor himself and one or two associated with him were prepared to harness their fortunes to the turbine.

However, though its early years were very anxious ones, the turbine slowly gained a place for itself as a prime mover of singular adaptability, and with the opening of the present century began that wonderful series of advances which has led to the steam turbine being without a rival for driving large electric generators and for propelling fast vessels. Parsons was thirty years old when he took out his first patents, and for the remaining forty-six years of his life, although he had many other interests, he was associated with every fresh advance and, as Sir Alfred Ewing said, was "the active and incessant *deus ex machina*". Others, too, made their contributions towards the progress of the turbine, but Parsons was ever in the forefront in all that concerned the design, manufacture, application and operation of turbine machinery. It was said in 1920, when he was awarded the Franklin Medal of the Franklin Institute of Philadelphia, that "it is no exaggeration to say that the work of Sir Charles Parsons has halved the cost of producing electric power and reduced in still greater proportion the capital cost of generating machinery". If that was true in 1920, it was still truer in 1931 when he died.

The early history of the turbine was dealt with by the late Sir Alexander Richardson in his excellent work "The Evolution of the Parsons Steam Turbine", published in 1911, at which time the finest turbines were to be found in battleships and liners such as the *Dreadnought* and *Mauretania*. The publication of this work has been followed by numerous papers read to technical societies and articles printed in technical journals, and now Mr. R. H. Parsons in this valuable volume on the development of the Parsons steam turbine has given a most able review of the history of the steam turbine as used in power stations, factories, works and mines during the past half-century.

It is explained in the preface that the contents of the book first appeared in a series of articles in the *Engineer* in 1934 and 1935, and that these articles described in chronological order most of the outstanding machines of their day. When they appeared, the articles were regarded as a notable addition to engineering history, and republished in book form they will be much more readily accessible for study and reference.

About two-thirds of the book is devoted to turbo-generators. Beginning with the early machines, Mr. Parsons deals in turn with radial flow turbines, parallel-flow turbines, single cylinder, two cylinder and tandem machines, and concludes with post-War developments and representative modern designs. There are numerous photographs and line drawings, particulars of tests and much interesting information on the design of the various details of both turbines and generators.

The story begins with the 7 kw. machine of 1884 and ends with the 50,000 kw. machines at Dunston and Chicago. Many of our finest power stations have been erected in the last ten years and therefore have but a short history, but there are others which have been supplied with turbines of various sizes over a period of thirty years. One of these is the Derby Power Station, and when describing the 20,000 kw. turbo-generator supplied to this station in 1928, Mr. Parsons gives a table showing particulars of twelve machines supplied between 1903 and 1928. This table is accompanied by curves illustrating the successive reduction in heat consumption and the improvement in thermal efficiency. The first machine at Derby, a 350 kw. direct current generator, had a heat consumption per kilowatt of more than 25,000 B.Th.U., while the corresponding figure for the 1928 machine was 11,710 B.Th.U.

From the first, Sir Charles Parsons saw that the turbine could be applied to marine propulsion and to various industrial purposes. With the second of these, Mr. Parsons treats in the latter part of his book, where he describes and illustrates turbine-driven pumps, blowers, compressors and the like.

Seen as a whole, the history of the steam turbine is a remarkable record of the result of inventive ingenuity combined with scientific investigation devoted to the solution of an urgent, practical problem. To some extent it has features in common with the history of the Watt engine. But whereas Watt worked at a time when mechanical engineering was in its infancy, Parsons began life when machine tools, workshop processes and steam machinery had reached a high stage of development. The difficulties Watt had to contend with were, in the circumstances, greater even than those Parsons had to face, but the histories of their respective inventions will ever remain as monuments to human genius.

Developments in Industrial Chemistry

(1) Sulfuric Acid Manufacture

By Andrew M. Fairlie. (American Chemical Society Monograph Series, No. 69.) Pp. 669. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1936.) 48*s.* 6*d.* net.

(2) Cours de chimie industrielle

Par Prof. G. Dupont. Tome 1: Généralités, les combustibles. Pp. vi+184. 35 francs. Tome 2: Les industries minérales. Pp. iv+337. 55 francs. (Paris: Gauthier-Villars, 1936.)

(1) ALTHOUGH the United States has for many years been the chief sulphuric acid-producing country in the world yet, curiously, its technical experts have, hitherto, omitted to make any notable contribution to the standard works dealing with the manufacture of this commodity. The advent of this monograph not only repairs this omission but also gives a welcome insight into the recent developments which have taken place in America.

The author has not intended to cover his subject exhaustively but has confined himself to a thorough treatment of the present-day manufacture of sulphuric acid. Although the work deals principally with American practice, nevertheless full descriptions are given, and adequate tribute is paid, in those cases where European methods differ from, or have advanced further than, those in the United States. Such differences are mainly to be found in those nitration processes which employ either the more intensive and space-saving chambers of the Mills-Packard and Gaillard-Parrish types or use towers instead of chambers.

In describing both the nitration and contact processes, the author first deals in detail with each step of the manufacture; these steps are then linked up and the working of the plant as a whole is discussed, together with the precautions to be observed when commencing operations, and the control which is necessary in order to secure maximum efficiency.

Considerable space is devoted to a thorough examination of the contact process, and the principal types of plant are illustrated from descriptions of actual installations. The various kinds of catalysts are set forth and their preparation given whenever this is known; there is also a highly interesting discussion on the advantages and disadvantages of platinum and vanadium catalysts.

Other sections deal with the concentration of sulphuric acid, the manufacture of oleum, hazards and safety measures, the shipping of acid and a system of cost accounting. The author also gives his opinion regarding the choice of process and the trend of future developments in the industry.

The book is profusely illustrated with photographs and diagrams, while a number of graphs and tables make it even more valuable to those actually engaged in the manufacture of sulphuric acid.

(2) These volumes represent part of a course given to students in the Faculty of Science at the University of Bordeaux, and in them the author has aimed at providing a link between pure and applied chemistry by endeavouring to show how the facts and theories of the former have been utilized industrially. Although such a course must of necessity deal comparatively briefly with the numerous industries described, yet Prof. Dupont has succeeded in including most of the recent developments. The work is thus admirably adapted to those embarking on a career either as technical chemists or chemical engineers, while it is also of value to anyone wishing to obtain a concise review of modern chemical manufacture.

The first volume is divided into two sections, the first of which deals with French company and patent laws and the administration and planning of factories; descriptions are also given of representative types of plant employed. The second part, which occupies about two thirds of the book, is given over to a wonderfully concise yet comprehensive study of natural and artificial fuels. Here are described the gas, tar-distilling and petroleum-refining industries, together with various kinds of producers and furnaces. The theoretical treatment is very thorough.

In the second volume are set forth the different inorganic chemical industries. The author first describes the liquefaction of air, the separation of its components and their uses, the production of oxygen, ozone and inorganic peroxides. The numerous processes for the preparation of industrial hydrogen are then discussed, while a subsection is devoted to the purification of water. The three following chapters, which deal respectively with the industries derived from nitrogen, sulphur and common salt, are probably the most important in this volume, covering as they do the bulk of the heavy chemical manufacture. They are excellently written, being models of terse description, although the theoretical considerations underlying the different processes receive adequate treatment. The remaining sections deal with fertilizers, with cements and with the glass and ceramic industries.

In view of the utility of these two volumes, it is a pity that they are but indifferently bound in paper covers and have uncut pages. Apart from the question of durability, even a mere chemist takes pleasure in the appearance of his library, and likes sometimes to say with Samuel Pepys, "My book is brought home handsomely bound, to my full content". G. R. D.

General Smuts

General Smuts
By Sarah Gertrude Millin. Vol. 1. Pp. xv + 394 + 12 plates. Vol. 2. Pp. xi + 496 + 11 plates. (London: Faber and Faber, Ltd., 1936.) 18*s*. net each.

FEW careers provide such a romantic story as that of General Smuts, and a biographer could scarcely fail to give a fascinating narrative from such a wealth of material. Yet with a man so versatile and manysided as General Smuts, that very wealth of material may prove the biographer's undoing, and while the scientific worker will appreciate the picture Mrs. Millin gives of the statesman, he can scarcely fail to lay down these volumes with a feeling of disappointment that so little justice has been done to the philosopher. One searches these volumes in vain for any comment upon the selection of General Smuts by the British Association to fill the office of president in its centenary year, and the philosophical views which Smuts has expounded under the name of holism receive scanty treatment.

Here as elsewhere Mrs. Millin fails in her interpretation, and gives rather a series of brilliant snapshots than the intimate and discerning study for which one had hoped. The book undoubtedly gives an arresting picture of the soldier and statesman, but Mrs. Millin's opinions are scarcely held sufficiently in check and at times she seems to lack the essential sympathy with her subject. Nor does she show full appreciation of some of the most significant of his contributions in the field of statesmanship. Only the briefest quotation is given from his outstanding Sidgwick Memorial Lecture on "Democracy" in which probably even more than in his later rectorial address on "Freedom" at St. Andrews, General Smuts gave the fullest expression to his political thought and his vision of the way in which the scientific and technical expert might be associated with the task of government in a democracy That conception may well prove to be one of Smuts's outstanding contributions to political thought if civilization proves able to weather the storms which immediately beset it. So, too, one might have expected a more generous account of Smuts's share in the shaping of the League Covenant and of the mandates article in particular, of his views on native policy and the relations between black and white races in Africa and of the contribution of science in the administration of the backward races.

The scientific worker cannot but regret that so little justice has been done to Smuts's constructive thought in such matters. None the less, he will appreciate to the full the moving picture which Mrs. Mullin has given us of one who throughout his varied experiences has brought steadily to bear on life a spirit of adventure, of willingness to face change, to abide by the results of scientific inquiry —a genuine capacity to see life steadily and to see it whole. These are of the spirit of science, and no one can lay aside the book without reflecting that in a like union of character and the capacity for generous co-operation and scientific insight may well lie our hope of leadership adequate to save the world from the dictatorships which threaten its noblest heritage of liberty and culture.

R. BRIGHTMAN.

An Illustrated Manual of Pacific Coast Trees

By Prof. Howard E. McMinn and Evelyn Maino. With List of Trees recommended for various uses on the Pacific Coast, by Prof. H. W. Shepherd. Pp. xii+409. (Berkeley, Calif.: University of California Press; London: Cambridge University Press, 1935.) 16*s*. net.

Of the numerous works dealing with trees and shrubs, there are few of pocket size which cater specially for the needs of the amateur botanist and garden enthusiast. Prof. McMinn's small manual is to be welcomed accordingly. Though intended primarily for use on the pacific seaboard of North America from British Columbia southward, the inclusion of a large number of cultivated trees will extend its sphere of usefulness. It will not, however, be of special value in Great Britain.

Artificial keys are used for distinguishing both genera and species. The generic key makes almost exclusive use of vegetative characters, and is simple and easy to use. Characters of the reproductive parts are employed more often for identifying the species. The keys are generally accurate, but exception must be taken to the separation of the English elm from the slippery elm by the presence of corky wings on the branches. It is curious indeed if the somewhat rare corky-barked variety of the British *Ulmus procera* Salisb. should be the common type in cultivation west of the Rockies. The ambiguous name *U. campestris* L. is adopted for this species, with *U. procera* Salisb. bracketed as a synonym. A number of similar errors are caused by following the list of "Standardised Plant Names" of the American Joint Committee on Horticultural Nomenclature. To the fault of the same authority is due the decapitalization without exception of all specific names.

The book is liberally illustrated with original line drawings of leaves, fruits and flowers, which supplement the short descriptions in the text. The marginal veinlets are frequently drawn in the leaves with great care, although no use is made of vein characters for diagnosis. A further interesting feature is an appendix of twenty-nine pages. This gives lists of trees suitable for particular purposes and adapted for growth in a variety of soil types from dune sand to alkali soils.

Les races humaines

Par P. Lester et Prof. J. Millot. (Collection Armand Colin: Section de biologie, No. 192.) Pp. 223. (Paris: Armand Colin, 1936.) 10.50 francs.

Repercussions of political events have brought about a general stocktaking in racial studies, of which the most important result has been that it has constrained anthropologists to clarify and restate their views on the definition of race, the essential qualities, or characters, on which racial classification is based, and on the classification of existing races. Numerous manuals have appeared with the object of removing misapprehensions among the general public as to the character and implications of the term, when used in the strict and only sense which can be regarded as applicable to *Homo sapiens* according to his physical characters.

Among such manuals a high place can be assigned to "Les Races Humaines" by MM. Lester and Millot. It is eminently sane and well-balanced; and it has the advantage for the layman that it does not confine itself to anatomical characters. By its treatment of the racial aspect of physiological studies, in such matters as growth, the blood-groups, metabolism, the nervous system and a number of related subjects of investigation, it indicates that racial studies cover an extremely wide and varied group of phenomena, which, as yet, affords little ground for confident generalization.

Here the view of the authors, put briefly, is that 'race' is not stable, and that as a basis of classification of the varieties of man, it has, so far as our present knowledge goes, little more than methodological validity.

Textbook of Quantitative Analysis

By Prof. William Thomas Hall. Second edition. Pp. ix+350. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1935.) 15*s*. net.

Prof. Hall's book, which is divided into two parts, provides a course of elementary quantitative analysis and a course of analyses of technical products corresponding with works laboratory practice. In both parts it is marked by careful description and emphasis on points which usually give trouble to students. A large amount of very sensible practical advice is given without running into the fault of some American practical books of labouring the obvious.

The theory is equally satisfactory; as examples, the discussions on *p*H values and indicators, on oxidation and reduction, and on the theory of electrolytic separations may be mentioned. The descriptions of the manipulations give all the necessary details, so that the student using the book should be able to make good progress without too much personal attention from the demonstrator. The reasonable price of the book is deserving of mention.

Distillation

By Prof. Joseph Reilly. (Methuen's Monographs on Chemical Subjects.) Pp. viii+120. (London: Methuen and Co., Ltd., 1936.) 3*s*. 6*d*. net.

The book under notice contains a mathematical account of the theory of distillation, the theory of fractionating columns, and a discussion of the apparatus and methods involved in distillation, both laboratory and industrial. The section on low-pressure distillation is of particular interest, since some modern industrial processes, such as the purification of vitamins, depend upon this process. The separation of liquids by the principle of azeotropic mixtures is dealt with fairly fully, especially as it concerns the dehydration of alcohol, which is becoming important with the use of 99–100 per cent alcohol for motor fuel.

There are also sections on destructive distillation and on sublimation. The book is well illustrated and gives a competent survey of the modern processes of distillation.

Natural Selection and Evolutionary Progress*

By Dr. J. S. Huxley

MULTIFORMITY OF EVOLUTION

THE students of a particular aspect of evolution are prone to think that their conclusions are generally applicable, whereas they usually are not. The palæontologists unearth long evolutionary series and claim that evolution is always gradual. However, their conclusions apply almost entirely to abundant and mostly to marine animals. In some land plants, on the contrary, we now have evidence of a wholly different method of evolution —namely, the discontinuous and abrupt formation of new species. In rare forms the course of evolution will not run in the same way as in abundant and dominant types.

Meanwhile the naturalist and the comparative physiologist are struck by the adaptive characters of animals and plants: to them the problem of evolution becomes synonymous with the problem of the origin of adaptation. The systematist, on the other hand, is struck by the apparent uselessness of the characters on which he distinguishes species and genera.

The palæontologist, confronted with his continuous and long-range trends, is prone to misunderstand the implications of a discontinuous theory of change such as mutation, and to invoke orthogenesis or Lamarckism as explanatory agencies: and, since there exist more rare than abundant species, the biogeographer will have to discount the fact that he is dealing mainly with processes irrelevant to the major trends of evolution regarded as a long-range process.

SELECTION IN A MENDELIAN WORLD

In our attack upon the problem, we must first mention some implications of recent genetics. Essentially, the modern conception may be put as follows. The notion of Mendelian *characters* has been entirely dropped. Instead of a given gene having a constant effect, its actual effect is dependent upon the co-operative action of a number of other genes. Mutations which in one gene-complex are pathological, in another may be perfectly harmless, and in yet another advantageous. The adjustment of such mutations to the needs of the organism may occur entirely through recombination of existing modifiers, or, after a preliminary and partial buffering by this means, the final adjustment may have to wait upon further mutation.

Thus, evolution need not occur by a series of sharp single steps; each such step is immediately *buffered* by ancillary changes in genes and gene-combinations. What evolves is the gene-complex; and it can do so in a series of small if irregular steps so finely graded as to constitute a continuous ramp.

Nor is the pathological character of many mutations at their first appearance necessarily a bar to their final evolutionary utilization by the species. The mutant gene *eyeless* in *Drosophila* was originally described as considerably reducing the size of the eyes, in some cases to complete absence, markedly decreasing fertility, and depressing viability. When, however, a stock for eyeless was inbred for a number of generations, it was found that practically all had normal eyes and showed little reduction in either fertility or viability. On outcrossing to the normal wild type and re-extracting the recessives in *F*2, it was found that these once more manifested the original characters of eyeless, though in even more variable degree.

The explanation of these facts is that the manifestations of eyeless are readily influenced by other genes, and that in general those modifiers which make for normal viability and fertility also make for normality in eye-size. Thus, natural selection acting upon the recombinations of modifiers present in the stock speedily saw to it that the combinations making for the manifestation of reduced eyes were eliminated. In competition with the wild-type allelomorph, eyeless would be eliminated; but in stocks pure for eyeless, the genes to be eliminated will be the plus modifiers of the mutation.

Selection of this type, it now appears, is a constant and indeed normal process. It has become almost a commonplace in animals used for genetic analysis to find that mutant types which at first are extremely difficult to keep going, after a few generations become quite viable. This has repeatedly occurred in *Gammarus*, for example, as well as in *Drosophila*, and is also known in mice and nasturtiums. R. A. Fisher has extended this concept to explain dominance and recessiveness in general. These are to be regarded as modifiable characters, not as unalterable inherent properties. Dominant genes, or most of them, are not born dominant: they have dominance thrust upon them. Mutations *become* dominant or recessive, through the action of other genes in the gene-complex.

---

* From the presidential address to Section D (Zoology) of the British Association, delivered at Blackpool on September 10.

In addition to the initial or intrinsic usefulness of a few small mutations, we have also the fact that mutations which are initially deleterious may become advantageous either in an altered environment or in an altered genic background, and the further fact that many mutations or Mendelizing variations cannot be described as intrinsically useful or harmful, but vary in their selective effects with variation in environmental conditions.

We must now discuss the processes of evolution and the role which selection may play in them. Darwin himself happened to confuse the issue by calling his greatest book the "Origin of Species". Evolution, however, must be dealt with under several rather distinct heads. Of these, one is the origin of species—or we had better say the origins of minor systematic diversity. Another is the origin of adaptations. A third is extinction. A fourth, and in many ways the most important, is the origin and maintenance of long-range evolutionary trends.

THE ORIGINS OF SPECIES

First, then, we have the origin of species. It is logically obvious that every existing species must have originated from some pre-existing species, but equally clear on the basis of recent research that it may do so in one of several quite different ways. A single species as a whole may become transformed gradually until it comes to merit a new specific name. Or it may separate, also gradually, into two or more divergent lines. Or it may hybridize with another species and the hybrid product then, by doubling of the chromosomes (allopolyploidy), give rise at one bound to a new species. Here, instead of one species diverging to form two, two converge to form one. So far, convergent species-formation is known only in plants. In these cases hybridization, apparently involving many more than two forms, together with recombination, chromosome-doubling and apogamy, appears to have been, and still to be, at work. A similar process, but without chromosome-doubling and apogamy, occurs in man. Thus species-formation may be continuous and unilinear; continuous and divergent; abrupt and convergent; or what, following a recent writer, we may call reticulate, dependent on constant intercrossing and recombination between a number of lines, and thus both convergent and divergent at once.

Divergent splitting must clearly be postulated on a large scale, if only to account for the rapid increase of the number of forms in newly evolved groups such as the higher placental orders. What without question are different stages of the process are yielded by a study of geographical distribution. Physiological subspecies are of a similar nature.

In all these cases isolation, whether geographical or physiological, is involved. We cannot be sure whether isolation simply makes it easier for selection to cause adaptive divergence in relation to local conditions, or whether in some cases at least, by some method as yet obscure, it permits the fruition of mere random and biologically useless variation. It does not matter in principle whether isolation is effected gradually or abruptly; in any case subsequent divergence will be gradual (except the cases of convergent species-formation, where the isolating process itself produces marked differences in appearance).

Biologists have realized for some time that the term *species* is loose and difficult of definition. However, whether we can define species or not, or whether we ought to emphasize the distinctions between different kinds of species by refinements of terminology, it remains true that species are genuine biological units. On the other hand, we can distinguish in principle between the causes of their isolation and the causes of their divergence.

From the point of view of natural selection, species will then fall into two contrasted categories. On one hand we have those in which natural selection can have had nothing to do with the origin of the basic specific characters, but merely acts upon the species as given, in competition with its relatives. These include all species in which character-divergence is abrupt and initial. On the other hand, we have those forms in which character-modification is gradual. Here natural selection may, and on both deductive and inductive grounds often must, play a part in producing the characters of the species. This helps to bring home the heterogeneity of the processes which we lump together as 'evolution'.

ADAPTATION AND SELECTION

We next come to the origin of adaptations. How has adaptation been brought about? Most biologists look askance at orthogenesis *sensu stricto*, and also at Lamarckism. As Fisher has cogently pointed out, the implications both of Lamarckism and of orthogenesis run directly counter to the observed fact that the great majority of mutations are deleterious.

There remains natural selection. We must invoke natural selection whenever an adaptive structure involves a number of separate steps for its origin. A one-character, single-step adaptation might clearly be the result of mutation. But when several or many steps are involved, it becomes inconceivable that they shall have originated simultaneously. The improbability is therefore enormous that they can have arisen without the operation of some agency which can gradually accumulate and combine a number of contributory changes: and natural selection is the only such agency that we know. Natural selection achieves its results by giving probability to combinations which would otherwise be in the highest degree improbable.

This important principle clearly removes all force from the 'argument from improbability' used by many anti-Darwinians, such as Bergson. It helps us also to detect the fallacy sponsored by T. H. Morgan, who has asserted that natural selection merely preserves certain among the hosts of recombinations, and that, in the absence of natural selection, in addition to the known forms of life a vast assemblage of other types would exist which have been destroyed by selection.

According to the view of the pre-adaptationists, variations occur which would be adaptive in some new environment or way of life, and their possessors then find their way into that environment or take up that way of life. What we have previously said makes it clear that this can only apply to the early stages of an elaborate adaptation, not to its whole history. Mutations, however, do occur which may be described as *potentially pre-adaptive*.

In general, the evidence that we possess goes to show, first, that selection can be very efficacious in altering the mean of a population within the range of existing variability; secondly, that a relaxation of selection will allow the type to deviate away from adaptive perfection, quite outside the range of variability to be found where selection is more stringent; and thirdly, that adaptive characters may advantage their possessors in such a way as to exert definite selection-pressure in their favour, and that accordingly selection can have a continuous guiding effect towards adaptive perfection.

EVOLUTIONARY TRENDS

We must now consider long-range evolutionary trends. It is quite clear that many of these are adaptive. So obvious is this fact that it has found expression in the current phrase *adaptive radiation*.

It is hard to understand why the trends seen in adaptive radiation have been adduced as proof of internally determined orthogenesis. Whenever they lead to improvement in the mechanical or neural basis for some particular mode of life, they will confer advantage on their possessors and will come under the influence of selection; and the selection will continue to push the stock further and further along the line of development until a limit of perfection, usually determined by quite simple mechanical principles, has been reached.

The only feature inviting orthogenetic explanation is the directive character of the trends. But on reflection this too is seen to be not only explicable but also expected on a selectionist point of view. Specialization, in so far as it is a product of natural selection, automatically protects itself against the likelihood of any change save further change in the same direction.

However, that this apparent orthogenesis is determined functionally is excellently shown by the evolution of the elephants, during which the effective reach of the animals for their food was continuously increased, but the structural basis was wholly altered. It is impossible to stretch the principle of internal orthogenesis to cover a process of this type.

The same principles would seem to apply in general to small-scale adaptations as to long-range adaptive trends, except that since such adaptations frequently concern only one particular function and not the organism's main way of life, it should be easier for evolutionary direction to be changed, and for adaptation to set off on a new tack.

An important difference will be found between abundant and scarce species. In the latter, competition will be more with other species, while in the former it will be more between members of the species itself. In general, this latter or *intra-specific* type of selection is more widespread than the inter-specific.

It is a common fallacy to think of natural selection as first and foremost a direct struggle with adverse weather, with enemies, or with the elusive qualities of prey. The most important feature of the struggle for existence is intra-specific competition.

It is another fallacy to imagine that because the major elimination of individuals occurs in one period of life, therefore selection cannot act with any intensity on the phase of minimum numbers. Selection, in fact, can, and does, operate equally effectively at any stage of the life-cycle. Further, elimination is far from being the only tool with which selection operates. Differential fertility of the survivors is also important, and in man and many plants is probably the more influential.

(*To be continued.*)

The Engineer and the Nation

IN his presidential address to Section G (Engineering) of the British Association, delivered on September 10, Prof. William Cramp took as his subject "The Engineer and the Nation" and, in the course of a very human and entertaining sketch, found opportunity to define the special functions of the engineer, to claim for him an appropriate degree of authority and independence in his own domain and to discourage the prevalent repression of technical knowledge and skill in the interest of commercial advantage or in favour of false standards of economy. The activities of the engineer, he holds, are closely linked with the national life and its progress and, to a very large extent, take the form of applying and bringing to the service of the community the knowledge previously gained by the physicist, the chemist and the metallurgist. He is not, however, detached from the work of fundamental research, for his training is in close touch with it and enables him frequently to bring to a conclusion the unfinished work of his collaborators in the field of pure science. As an instance of this, Prof. Cramp ascribed to the engineer the evolution of the Cooper-Hewitt arc rectifier from its humble beginnings to its present outstanding position as the most important converter in heavy electrical engineering.

The fundamental differences between those engaged in the pursuit of pure science and the engineer are to be found in the conditions under which they must work and in the ends toward which they strive. For the investigation and study of natural phenomena and their laws, the scientific worker requires quiet detachment and, for him, the main purposes are to know what is unknown, to observe behaviour, to determine natural laws, to construct a framework of principles fitting the collected observations. The engineer, on the other hand, must keep in close touch with the life and interests of the community, and the major part of his work is done under the conditions of intense and orderly bustle associated with construction. His aim is to apply knowledge, to link it with the experience of the ages, to utilize and to conserve the energy that is available for the increase of the amenities of life. In this way, engineering has become the greatest instrument of civilization the world has known; at least three-fourths of its work consists in making, maintaining and developing communications.

While it may not be possible to accede to Prof. Cramp's claim that, left undisturbed by politicians, scaremongers and patriots, the engineer would render war impossible, the thoughtful will be able to appreciate from the context of examples and suggestions the underlying truth and moral of his case. But whether in peace or in war, the products of the knowledge and skill of the engineer as a pioneer are vitally important, so to the nations and to the world at large his activities and the ends to which he directs them are matters of supreme concern. Thus it is that the man, the engineer, is at all times closely associated with human relationships, and his opportunities for development or loss of character are great; his chances of salvation and his risks of damnation are increased, for character does not mature in cloisters, and exposure is necessary for the proof of it.

Finding the engineer so privileged in the nature of the services he can render to the community, Prof. Cramp then asks to what extent do his fellow men recognize his real and potential importance, and how far does he abuse his position or allow himself to be made the tool of less scrupulous men. Although the period and extent of his training correspond to those of the doctor and lawyer, the engineer has no similar status nationally recognized, nor does he on the average receive the same rewards. Men responsible for the design of high-speed turbo-generators or for other work transcending that of the doctor in respect of the safety, not merely of individuals but of masses, may never receive more than £750 per annum. On the other side of the account, instances are given of unprofessional conduct; while it is out of place here to recapitulate details of the commercial practices of individuals, firms, and associations to which Prof. Cramp referred, it is to be hoped that his plea for a higher standard of integrity may have good effect and may assist in promoting the reforms he suggested.

In the forefront of these reforms Prof. Cramp places the need for a body with statutory powers to define the qualifications and status of those who may use the titles at present freely adopted, to prevent unqualified persons from jeopardizing life and also to check unprofessional conduct. Expressly it is stated that such a measure of immunity as has been achieved by the legal and medical professions is not desired. An urgent reform also is the proper representation of science on governing bodies in industry and in technical departments in the State and municipalities; and here it was suggested that the British Associations should take steps and also appoint a committee. Some means by which the engineer shall not be over-ruled in technical matters by the commercial man, drastic alteration of the patents procedure in the law courts and a suggestion for the revision of the constitution of the councils of the trade associations by making them representative of makers, contractors and buyers are also urged as much needed reforms.

Finally, there is the question of the general professional code. Backsliding, Prof. Cramp finds, can only be corrected by a higher training of character and, in his concluding words, "The remedy lies in the hands of parents and those who control educational institutions: it is urgent and of national importance. I commend its consideration to the Board of Education, the Committee of Vice-Chancellors, and to the members of Section L. British engineers have, in the past, earned a great reputation for reliability and straight dealing. This is a national asset of real value, which can only be maintained if, as in our national games, we learn to place integrity before self-interest".

The Place of Science in General History

A MARKED change has taken place in recent years in the attitude of the 'general historian' to natural science. Fifty, or even forty years ago, it was possible for S. R. Gardiner to write a history of England covering the life of Newton, and to allude to Newton only as Master of the Mint. To-day, in every book of similar scope and size, something would be said about the achievements of science in the seventeenth century, as well, probably, as something about the connexion of science with the industrial developments of the eighteenth and nineteenth. This is all to the good, and in the same direction should be noted the recent great interest in 'pre-history'. The last will probably prove in the end the decisive factor in changing the focus from which we regard the past, or rather—to use a more appropriate metaphor—the centre of gravity on which the past and present repose. As this is the capital point in the discussion, it will be best to make it clear at starting.

The older, and still prevalent, view regarded the agents and the machinery by which the government of nations is carried on as the dominant factor in human affairs. Hence, in practically all historical works of a general kind, the writer spent his chief, often his whole, pains in describing this type of action and the characters of those who did it. For this reason all of us have some sort of picture in the mind of the most eminent and interesting kings, emperors, soldiers and statesmen. They serve, of course, a very useful function as landmarks in the course of time, as *points-de-repère* round which we may collect the other fragments of knowledge which we possess. But the newer and truer point of view carries the matter a good deal further back. The really determinant factors in human life in the long run are more profound, more obscure and, above all, more purely mental. The revelations of pre-history make this clear. We find, probe as far as we may, that, millenniums ago, the mind of early man was at work making inventions and observations which laid the foundation of all the civilization which has followed. When we grasp this, we must be led on to see that the mental process is a continuous one and that the abstract-thinking mind becomes more, and not less, dominant as history proceeds.

The question, therefore, which every honest person must put to himself is this: Do we really desire to know the true connexions of things in the past, the authentic structure of the society of which we are a part, or do we prefer the superficially more exciting incidents which the novelist historians are always ready to turn out? Is it the 'private life of Henry VIII' and the mistresses of Charles II, or the scientific revolution which took place between those monarchs, which really interests us the most? All are a part of history, and all historians and readers of history must select.

One must not be understood to belittle the importance of the governmental side of history, or to be attempting to identify it with the personal foibles of its prominent actors. But it is necessary in the interest of truth to assert that hitherto there has been a vast miscarriage of interest and attention in this matter, which is a vital one for the intellectual integrity of the race.

How may the correction be best carried out, without revolution, and without lessening the total amount of interest which the thinking public is inclined to give to history?

In the first place, the change must take place gradually and by the mental conversion, both of those who write and those who read history. This follows from the very thesis that we are maintaining. Mind rules the world, and this is a case of men's minds awakening to the real nature of the process. Evidence is abundant that most of the competent minds which have turned to the subject now realize, more or less dimly, the nature of the truth, and the truth is spreading. Lord

Acton at Cambridge was the turning point in England. Few would now contend, with Seeley, that "history *is* political history". Or if a stray campaigner, like Sir John Marriott, is found to say so, he can only be understood to mean that 'the history *I* write, or am interested in, is political history'. Most students of history would now admit our general thesis on Acton's lines and add that they personally, not being competent in mathematics or physical science, prefer to leave such parts of the historical field to those who are. Thus, though the battle has been won in the main strongholds, it remains to carry out the organization and administration of the conquered area in the new spirit, and this will take time and various expedients. A few may be suggested.

In large encyclopædic works, like the "Cambridge Modern History", separate chapters may be, and are, included on science, as on art, etc., by specialist writers, in the midst of the main current or political and social history. This is much better than nothing, but does not meet the need of synthesis in treatment, or of showing how the scientific spirit has made itself felt in the realms of government, religion or social life. The work is much better done when the historian, though he may not have had a scientific training in his youth, applies his own mind to the subject and does his best as one man. G. N. Clark's "History of the Seventeenth Century" is a very spirited and successful essay of that kind. On a much larger scale, Preserved Smith's "History of Modern Culture" goes even too far in the other direction, for, by not preserving any political outline, it rather loses the sequence and position of events. Some such outline is necessary to keep our minds in order, though there is no need that it should be the old dates of kings and queens, and increasingly, in the future, history will need fresh landmarks.

That the student and writer of history should be, if not personally trained in science, at least in constant mental contact with those who are, is of course the only right way. But it should not be forgotten that the student of science may be himself as much of a narrow specialist as any student in the Record Office. Both need the philosophic view, that is, the constant and sincere attempt to see things whole and in their relation to the whole.

Now seeing things whole in history leads to sociology, if indeed it is not the best definition of what sociology aims at. Therefore it is relevant to our subject to point out that there is at present only one chair of sociology in Great Britain, that founded at the London School of Economics by the late Mr. Martin White. It would undoubtedly tend to a more synthetic view of history (which includes putting science in its due place) if wealthy and enlightened donors could be found to institute other chairs, and above all at the two older universities. Meanwhile the keen prosecution of anthropology, fostered especially at Oxford by Dr. R. R. Marett, is doing something to fill the gap. It is not suggested that sociology should control the teaching of history but, being essentially philosophic and connected with all the branches of the study of man, it acts as a link and promotes the synthetic view among all who come in contact with it.

For this must be the final and guiding thought in the minds of those who wish to see science occupy its true place in our view of the past. We welcome its recognition, even in the disconnected form in which it generally appears. But this is merely the first step, and by itself not of much significance. Integration is needed: not the extra chapter inserted in the general survey, narrating the discovery of the spinning jenny or even how Watt was helped by Black in developing the steam-engine, but a consideration of the social origin and social effect of these things. They go back to the roots of man's thinking; they go forward indefinitely, modifying the way in which he lives and regards the world.

The line of demarcation does not seem too difficult between what may be expected in general history about science and technology and what is properly left to specialist works. It would be improper and absurd to include the detailed theorems of Euclid or the drawings for Watt's steam-engine in a work on general history. But one should be able to gain some idea of how Greek geometry arose and what it meant for the unification of ancient thought, and, in the latter instance, it is essential that one should be led to think how modern inventions have been conditioned by science and what changes and problems have been laid upon us by a mechanized world.

The students and writers of history are still only at the threshold of this inquiry, but it is a welcome advance to have come in sight of it. There is now a lively demand for some teaching as to the history of science, which is taking shape in Cambridge this term in a new series of regular lectures. Prof. Lancelot Hogben expressed the same desire in his recent lecture on the "Retreat from Reason". But most vital of all would be the enlistment of the body of general historians in the cause. They have the historical spirit and the technique. We owe mainly to them the general interest and respect for the past which distinguishes our country. An alliance between the two forces, and an enlargement of the old historical discipline, would be an educational revolution of the most far-reaching type.

Obituary

The Right Hon. Lord Moynihan, K.C.M.G., C.B.

LORD MOYNIHAN died on September 7 at his home, Carr Manor, Leeds, in his seventy-first year. His fame was world-wide, and great gifts with which he was endowed made him the greatest surgeon of the day both in Great Britain and abroad. His father was Captain Moynihan of the 8th Foot, who gained the Victoria Cross in the Crimean War. Ten years later, on October 2, 1865, Berkeley Moynihan, his only son, was born at Malta. He was educated at the Royal Naval School and entered the Leeds Medical School for his professional training. He took his M.B. at the University of London in 1887 and the fellowship of the Royal College of Surgeons of England in 1890. After graduation he started teaching anatomy in the Leeds Medical School; later he was appointed assistant surgeon to the Leeds General Infirmary and then in due course surgeon and consulting surgeon and professor of surgery in the University of Leeds.

Moynihan's success as a teacher and reputation as a surgeon brought him early a lucrative practice in the north of England, and he was rewarded with a knighthood in 1912. During the Great War he was appointed consulting surgeon to the Northern Command, and later, consulting surgeon to the British Expeditionary Force, with the rank of Major-General A.M.S. He was made K.C.M.G. in 1918 and a baronet in 1922. In 1929 he was created Baron Moynihan of Leeds, the only surgeon with the exception of Lister to receive a peerage. At the Royal College of Surgeons he passed successively through all the offices and held the post of president for six years (1926–32), a longer time than any of his predecessors.

Many qualities contributed to make Moynihan the man he was. Physically he was strong, rarely ailing and possessed of abundant energy and vitality. Cheerful in disposition and willing to please, he was eager to be liked. Perhaps this was the Irish element coming out in him. It is to his credit that though he loved to please, he was just as pleasant to an omnibus conductor as he was to a titled patient. Mentally he was alert, quick-witted and ready to seize a new idea, make it his own and improve on it. As a speaker he was pre-eminent. His addresses and speeches, of which he made many, though carefully prepared, were delivered in faultless manner without a note, and their charm and persuasiveness were enhanced by a full melodious voice.

These attributes, great as they were, would not have led to Moynihan's high position if it had not been for his great powers as a surgeon. In the early years of this century his fame was growing, and a visit to Leeds to see Moynihan at work became a routine for surgeons visiting England from abroad and especially for surgeons from the United States, amongst whom he had many friends and with whom his reputation stood high.

The reason for this high reputation may be ascribed in the first instance to technical skill. Moynihan was a master in technique and it was a joy to watch him at work. There was nothing of the slapdash, cut-and-thrust method of the pre-Listerine surgeon. Instead infinite patience and infinite gentleness, by which means difficult and dangerous operations were brought in his hands to a happy issue where more rapid but rougher surgeons failed. Moynihan saw also the great value of careful preparation before operation so as to bring the patients into the most favourable condition, and to this end he devoted as much attention as to the operation itself. To use his own words, he raised his surgery to the sanctity of a sacrament.

But Moynihan was more than a deft user of his hands. He was intensely interested in the scientific side of his profession and made considerable contributions to clinical science which of themselves entitle him to fame and to rank with the Masters of Medicine. The most important of these are in connexion with diseases of the duodenum, stomach and gall bladder. The recognition of duodenal ulcer and its successful treatment we owe to Moynihan. By skilfully correlating the symptoms as related by patients and observations made in the operating theatre, he drew a clinical picture of the disease by which it can now be recognized with ease and accuracy.

The operation of gastrectomy for gastric ulcer received a great impetus in the hands of Moynihan. He picked up the idea, probably, from Polya, but he modified and improved it and, what is more, taught other surgeons to do it too. Other important contributions were made on diseases of the spleen, pancreas and gall bladder, and again he showed that the morbid condition was characterized by a definite clinical picture.

By these means Moynihan was led to inculcate a doctrine, the truth of which is being but slowly admitted, that there is a pathology of the living, distinct from the autopsy chamber. He held that the beginnings of disease processes should be studied while patients are yet alive, and that the best place to study these is the operating theatre, which he termed his laboratory.

Associated with this technical excellency was a power of organizing ability. Many years ago Moynihan realized that in order to raise the standard of surgery throughout Great Britain—and this ideal was very near his heart—it was essential not only to have a high individual standard, but also to create a free intercommunication and a comradeship between surgeons. He described these ideas in a letter written only last May. He writes:

"In my early days I was struck by the lack of cohesion among members of my profession. Surgeons in one town knew little or nothing of surgeons elsewhere. A surgeon from Manchester had never, so far as I could hear, visited an operation theatre in Leeds, nor had one ever been called in consultation.

As a consequence it was not infrequent to listen to disparagement of one surgeon by another and jealousies openly expressed were too often heard. I thought this all wrong. If we were indeed members of a 'noble profession' as we most certainly were, then it was clearly an obligation upon us to speak well of one another. It seemed to me that if by any means we could be brought together, it would be a great advantage to us all and that we should then be made to realize that we were not competitors, one working against another, but comrades, each working with the others against the common enemy, disease."

The means that Moynihan took to accomplish his ideal were three. First came the foundation of the Provincial Chirurgical Club (since 1929 called the Moynihan Chirurgical Club). This body of surgeons met among themselves, visited each other's clinics as well as foreign cities. In this way the most important surgeons all over the world were visited, and Moynihan may be regarded as the finest medical ambassador England ever had. The second method was the establishment of the *British Journal of Surgery*, which under his chairmanship reached the proud position of the premier surgical journal. The third means and the most important, and one in which Moynihan took a prominent part, was the foundation of the Association of the Surgeons of Great Britain and Ireland. This has proved a great success and drawn together surgeons from all over the country, raised the standard of British surgery and removed the reproach of "lack of cohesion" among members of the profession.

One of the most important works of Moynihan's life and one of which he did not live to see the full fruits was the introduction of the study of experimental surgery. Moynihan saw that if surgery is to continue active and progressive, an intensive and direct study must be made of the many problems which confront the surgeon. During his time as president of the Royal College of Surgeons, he devoted time and energy to securing surgical research scholarships and laboratory accommodation where young men entering on the surgical profession might be trained in methods of research. His efforts were rewarded, and a flourishing school of this new science is growing up, the importance of which it is hard to predict.

Moynihan's life may be described as a success, a victorious success, and the world is the richer for his being. G. E. G.

Mr. E. R. Deacon, O.B.E.

We regret to record the death of Mr. Edgar Reginald Deacon on August 29. It may be recalled that during the early months of the Great War there was a serious shortage of high explosives; in particular, the supply of T.N.T. (trinitrotoluene) available was totally inadequate to meet the enormous requirements. It was early in 1915 that Deacon, whose province at the Research Department, Woolwich, had been the study of high-explosive munitions, made the suggestion that by mixing the available T.N.T. with ammonium nitrate it could be made to go much farther without loss of efficiency, a fact which he demonstrated experimentally. At the outset he suggested the mixture of equal weights of these materials, this mixture having the advantage that it could be filled into shell by casting in a manner similar to that hitherto used for lyddite. Within two months he had worked out the more difficult problem of preparing and filling a mixture of 80 parts of ammonium nitrate and 20 of T.N.T., which contained too much ammonium nitrate to be cast. This advance made it possible to fill five times the number of shell hitherto possible with a given weight of T.N.T.

The importance of these suggestions was immediately recognized by his chief, Dr. (now Sir) Robert Robertson, who took steps to develop these mixtures further and brought them to the notice of the Ordnance Committee and Lord Moulton. In this way, birth was given to that important series of explosives later known as the amatols. Rapid expansion of the use of amatol followed in the national filling factories under the Ministry of Munitions, and many individuals contributed with great skill and ingenuity in furthering its successful application. It was used not only for shell but also for other munitions such as bombs, mines and torpedoes, and it has been estimated that no less than 600,000 tons were used by the British Services during the War.

The importance of the introduction of amatol is indicated by a speech made by Lord Moulton in 1917 in which he referred to two inventions brought forward by the Research Department, 40/60 and 80/20 amatol. By means of these he was enabled to meet his obligations, especially with 80/20, which effected such a great saving in the use of T.N.T. He recalled the advocacy of the Research Department of this explosive, which he considered to be "the greatest single thing in importance in the supply of that wealth of munitions that has enabled our armies to expend shell to an unlimited extent".

Edgar Reginald Deacon was born in 1881 at Frome, educated at Sexey's School, Bruton, Somerset, and later studied at the Finsbury Technical College. For some time he held appointments as assistant to the late Mr. Chaston Chapman and as assistant chemist at the Clinical Research Association. In 1902 he joined the staff of the recently formed Experimental Establishment (now Research Department) at the Royal Arsenal, Woolwich, in which he remained until his death.

Deacon devoted many years to the study of high-explosive munitions and for more than twenty years was head of the high-explosives branch of the Directorate of Explosives Research. He was elected fellow of the Institute of Chemistry in 1917 and awarded the O.B.E. in 1918.

Deacon was highly original and full of resource, and many important improvements in the efficiency and safety of munitions are due to his work. The Fighting Services have lost a most valuable servant. To quote from a letter received from another Government Department: "All who had official dealings with Mr. Deacon will gratefully remember his wide knowledge, wise counsel and willing helpfulness."

News and Views

Awards for Cancer Research

THE International Union against Cancer, of which the headquarters is in Paris, has awarded a prize for scientific work on cancer to Profs. E. L. Kennaway and J. W. Cook of the Research Institute of the Royal Cancer Hospital (Free), Fulham Road, London. The prize, which is the gift of the Union Minière du Haut Katanga, the well-known Belgian firm engaged in the production of various metals including radium, consists of 50,000 francs together with 50 milligrams of radium for use in research work. The presentation was made last week in Brussels during the Second International Congress on Cancer by Dr. Jacques Bandaline, the director of the Bureau of the International Union against Cancer, in the presence of the Prime Minister of Belgium and numerous delegates to the Congress. Mr. Cecil Rowntree, senior surgeon to the Royal Cancer Hospital, and a representative of Great Britain on the International Union, read a telegram of congratulation from the Earl of Granard, the president of the Hospital. Prof. Cook, in expressing thanks for the award, paid a tribute to the essential part played in the development of the research by four colleagues, Drs. Mayneord, Hieger, Hewett and Haslewood. Prof. Kennaway was educated at University College, London, New College, Oxford, and the Middlesex Hospital. He is professor of experimental pathology in the University of London and director of the Research Institute of the Royal Cancer Hospital (Free), London, and is author of several papers on biological chemistry and cancer. Prof. Cook, who was educated at University College, London, is research chemist at the Royal Cancer Hospital, and is professor of chemistry in the University of London. He is also an honorary secretary of the Chemical Society. He has written numerous papers on organic chemistry, particularly in relation to cancer.

Bust of Kelvin for the Smithsonian Institution

THE presentation of the bronze bust of Lord Kelvin, by the late Herbert Hampton, to the Smithsonian Institution, is to take place on October 8 at Washington, D.C. The English-speaking Union has arranged a luncheon at the Hotel Willard, Washington, in honour of the occasion, at which Dr. C. G. Abbot, Secretary of the Smithsonian, will receive the bust. Mr. V. A. L. Mallet, counsellor of the British Embassy at Washington, will transfer the bust on behalf of the English-Speaking Union of the British Empire to the English-Speaking Union of the United States. Dr. W. F. G. Swann, of the Bartol Research Foundation, acting as the American Union's spokesman, will then officially make the presentation to the Smithsonian Museum, and Dr. Abbot will reply. The bust was dispatched from England on September 23. It is to receive a prominent position at the Smithsonian Institution, and it is hoped that it will form the nucleus of a permanent exhibit to be collected indicative of Lord Kelvin's contributions to various branches of science on both sides of the Atlantic. The late Herbert Hampton, the famous sculptor and friend of Lord Kelvin, made this bust from life in 1902, five years before Lord Kelvin's death. It has never been cast before, although it was used as a model for the bas-relief on the Queen Victoria Memorial at Ipswich. The plaster cast was carefully preserved by the sculptor's widow, from which a bronze has now been cast for the Smithsonian. Hampton was well known for his public memorials and portrait busts of celebrated people. His works include five memorials to Queen Victoria, statues of King Edward VII and King George V, the well-known figure of the Duke of Devonshire in Whitehall, the Marquess of Salisbury (at the Foreign Office) and Lord Hardinge (at Bombay).

Wilhelm von Waldeyer (1836–1921)

OCTOBER 6 marks the centenary of the birth of the eminent anatomist, embryologist and anthropologist, Wilhelm von Waldeyer, who was born in the village of Hehlen in Brunswick, and died on January 23, 1921. He first devoted his attention to natural science and mathematics, but under the influence of Henle took up medicine, which he studied at Göttingen, Greifswald and Berlin, where he qualified in 1861. After acting as von Wittich's assistant at the Konigsberg Physiological Institute, he went to Breslau in 1864 where he was first assistant to Heidenhain; then he became extraordinary professor of morbid anatomy in 1865 and full professor in 1867. In 1872, he was appointed professor of normal anatomy at Strasbourg and was transferred in 1883 to the corresponding chair at Berlin, which he occupied until 1917. His literary output was considerable, as is shown by the bibliography of 269 references in Sobotta's memoir (*Anatom. Anzeiger*, 1923). His principal works were on the ovary and ovum (1872), sclerotic, cornea and conjunctiva (1874), an atlas of human and animal hairs (1884), a history of anatomical instruction in Berlin (1899) and Darwin's doctrine (1910). He also made important contributions to our knowledge of cancer, retroperitoneal hernia and pelvic viscera, and was the first to describe the neuron theory, the ring of lymphoid tissue in the pharynx and chromosomes. He was co-editor with La Vallette St. George of *Archiv für mikroskopische Anatomie*, Virchow-Hirsch *Jahresbericht* and *Archiv für Anatomie und Physiologie*.

"Natives" in Western Australia

UNDER the provisions of an Aborigines Bill introduced in the Legislative Council of Western Australia on September 23, it is now proposed that all people of colour in Western Australia, whether full-blooded or of mixed origin, shall no longer be known as "aborigines", "half-castes", or "near whites", but shall be termed "natives". While this proposal no doubt removes what has been felt in certain circumstances to be a stigma, it perpetuates and gives official approval to a troublesome ambiguity. The Bill was introduced on behalf of the Western Australian Government by the Chief Secretary, Mr. W. H. Kitson (*The Times*, Sept. 24). As it stands, the proposals deal with certain matters affecting the natives to which attention was directed recently in the drastic report of a commission of inquiry criticizing native conditions and the organization and functioning of the Western Australian Government's provision for the protection of the aborigines (see NATURE, **135**, 798). A better system of control of the natives is to be introduced; and a serious attempt is to be made to grapple with the grave problem of the conditions affecting native mothers and their children; while the employment of young females will be regulated to prevent exploitation by their employers. Other matters which come under view or revision are the terms of native tenure of property and land, the prohibition of the sale of intoxicants to natives, and the delicate question of the curtailment of tribal custom and practices which "are calculated to cause bodily injury or to militate against the Department's work of amelioration". Finally, and in view of past history, perhaps most important of all, native courts are to be established for the trial of offences committed by one native against another. From the brief summary which so far has been transmitted by cable, it would appear that the Government is making a determined effort to remedy the graver defects of its system to which attention has been directed, and that in certain respects the practice of the State will be brought into line with that of the Federal Government in its relations with the aborigines of the Northern Territory.

Foundation Rites at Maiden Castle, Dorchester

Two important discoveries mark the approach of the closing week of excavation at Maiden Castle, Dorchester, where Dr. R. E. Mortimer Wheeler is at work on behalf of the Society of Antiquaries and the Dorset Natural History and Archæological Society. The adult burial (see NATURE, Sept. 5, p. 395) is now found to date from the Iron Age *c.* 300 B.C. and to be situated at the base of the rampart of the earlier enclosure at the point of contact with the rampart of the larger and later Maiden Castle. The character of the filling of the grave indicates that it is contemporary with the construction of the latter, and its position, as well as the fact that it is the only adult burial so far discovered within the enclosure, fully justify the view taken by Dr. Wheeler that it may possibly have been a ceremonial burial connected with foundation rites, such as are known to have been observed elsewhere, to mark the first great extension of Maiden Castle. The second discovery is that of a third structure on the summit of the hill adjoining the Roman temple and contemporary with it. It is built of dry stone walling, without mortar, and is circular or polyhedral in form. Its character is still under investigation. Further details connected with the east gate have now been made clear. The southern of the two openings, which was previously thought to be an addition, has now been shown, it is reported in *The Times* of September 26, to be an original feature of the earliest structure, as a causeway of unexcavated chalk runs across the line of the ditch in front of it. This causeway was much mutilated in late Roman times, when the entrance was blocked by a masonry wall built with a core of chalk quarried from the causeway. The line of quarrying, associated with Roman material, has been discovered, and the excavation here is now nearly completed.

Archæological Investigations in the Northern Transvaal

REMARKABLE results obtained since 1933 in the excavation of two sites in the Zoutpansberg District, Northern Transvaal, have evoked so many inquiries that Prof. C. van Riet Lowe, director of the Bureau of Archæology, University of South Africa, has been authorized by the Archæological Committee of the University of Pretoria, the body conducting the investigation, to prepare a preliminary report, which appears in *Antiquity* of September. The two sites, Mapungubwe, and the adjacent and earlier site, Bambandianalo, are situated on a farm near the junction of the Shashi and Limpopo rivers, about one hundred and sixty miles south-west of Zimbabwe, and just over fifty miles due west of Messina, where there are extensive remains of pre-European copper workings. The farm is now the property of the Union Government, having been purchased on the urgent representations of Prof. Leo Fouché. This public-spirited action has proved of inestimable benefit to the advancement of archæological studies in South Africa by making possible the scientific excavation of sites hitherto undisturbed. Notwithstanding the spectacular situation of the Mapungubwe fortress with its dry-stone walling on an inaccessible sandstone cliff, one hundred feet high, and the wealth of gold and other cultural objects found here, in the associated cemetery, and on the earlier site of Bambandianalo (see NATURE, **137**, 1024), these sites do not differ essentially from other sites in the region and in Rhodesia, including the Zimbabwe explored by Dr. D. Randall-MacIver and Miss Caton-Thompson; but these latter have suffered from the disturbance of treasure hunters and unauthorized excavation. Hence it has now been possible to establish with certainty a cultural sequence, from which it is inferred that the earlier of the two cultures found here, that of a copper-working pastoral people, may represent the earliest wave of the incursion into what is now South Africa of the Bantu-speaking peoples.

New Aeroplane Height Record

ON September 28, Squadron Leader F. R. D. Swain, a test pilot at the Royal Aircraft Establishment, Farnborough, set up a new height record for aeroplanes when he ascended to 49,967 ft. According to *The Times* of September 30, Squadron Leader Swain was flying a low wing monoplane of wing span 66 ft. and length 44 ft. with a super-charged Pegasus engine designed to give 370 h.p. at the start, 457 h.p. at 40,000 ft. and 380 h.p. at 50,000 ft. The pilot was enclosed in an air-tight two-piece suit of fabric covered on both sides with rubber and surmounted by a helmet with a transparent window. His air supply was fed into the right side of the helmet and passed out on the left to a canister in which water vapour and carbon dioxide were removed before the air returned to the circulation. The cockpit of the aeroplane was also enclosed, and warmed from the engine exhaust. It appears that Squadron Leader Swain found no particular difficulty in the ascent, but when coming down, the window of his helmet and the cover of the cockpit were badly obscured by frost. He also experienced unpleasant sensations of suffocation accompanied by weakness, and was obliged to use his emergency knife to rip open his helmet. He landed safely after a flight lasting nearly three and a half hours. The height reached was nearly thirteen hundred feet above that attained last month by M. Georges Détré at Villacoublay, France.

Crop-growing without Soil

ATTENTION has recently been given to production of green fodder for cattle and other farm stock without the intermediary of the soil. In Great Britain the method advocated is apparently of German origin, and it is claimed that the fodder is grown from seed in ten days. According to published accounts, a layer of seed (maize or other grain) is spread on a perforated metal tray, and the tray is placed in a cabinet, constructed to hold a series of trays. The seed is damped daily by water, containing a small percentage of nutrient salts, from a tank placed on the top of the cabinet, and, when an adequate temperature is maintained, the seed germinates and in 10 days a growth of shoots some 12 inches high is obtained. This growth of shoots, with the mass of rootlets, is then given to the stock. Several trials have shown that this fodder is readily eaten by stock, but carefully controlled experiments are necessary to demonstrate the full nutritive value and the costs of production of this fodder. At the University of California experiments have been carried out by Prof. W. F. Gericke on the growing of vegetables and flowers in tanks of water to which the necessary chemical fertilizers have been added. The seeds are sown in a layer of sawdust or moss supported by wire netting above the water; the roots grow downwards and remarkably rapid growth and a high yield has been demonstrated. Although still in the experimental stage, this process has attracted the attention of commercial vegetable and flower growers in California.

Huskless Oats

DURING the past two years considerable public interest has been aroused in a variety of huskless oats introduced by Mr. William Parker of Babingley Hall, near King's Lynn. In 1936, with the agreement of the introducer, the National Institute of Agricultural Botany carried out accurate yield trials of this variety in Cambridgeshire, Somerset, Shropshire, Hampshire, Norfolk and Yorkshire. The rate of seeding (45 lb. per acre) and the sowing times (end of March and beginning of April) were those recommended by the introducer. The variety with which the oat was compared was Victory, and at each centre both were sown on the same day. Victory, however, was sown at the normal seed rate for that variety—3–4 bushels per acre. On the basis of grain as threshed, Victory outyielded Parker's Huskless oat by 97 per cent, but to obtain a true comparison 28 per cent must be deducted from the grain weights of Victory, this being the normal husk percentage of that variety. On this basis, at only one centre—Cambridge—did Parker's Huskless oat outyield Victory, and then by the insignificant amount of 2 per cent. Averaging the results from all six centres, taking both on the above basis of naked grain, the grain yield of Victory was 41·2 per cent heavier than Parker's Huskless oat. No shattering at harvest took place in either variety.

Research and the Jute Industry

A PARAGRAPH under this heading appeared in NATURE of August 22 (p. 322), based on an article in *Science and Culture* discussing Dr. S. G. Barker's recommendations for research in the industry. Dr. Barker has written to point out that his report was on "Jute Research" as affecting jute *manufacture*, and should not be confused with the report of the Bengal Jute Enquiry Committee, which was concerned with *agricultural* aspects. His report was submitted to the Indian Jute Mills Association, which is at present considering it. Whether it will be submitted to the Government of India is a domestic matter for the jute manufacturers to decide. On the other hand, the suggestions of the Bengal Jute Enquiry Committee regarding jute agriculture have been accepted by the Government of India and a committee formed to implement them. So far as manufacturing research is concerned, this is still under sympathetic consideration by the Indian Jute Mills Association.

Social Life in a Rural Community

A STUDY of the activities, interests and problems of young married men and women, 15–29 years of age, in the rural sections of Tompkins County, has been published by the Cornell University Agriculture Experiment Station, as part of a study of youth problems. The data were acquired by direct personal interview with each of the 347 persons included in the study. One third of the persons interviewed were men and two thirds were women. Of the whole group, 30 per cent lived on farms, 40 per cent in villages and 30 per cent lived in the open country but not on farms. On an average, these young people had spent more than two years at a high school, and two in five of the men and one in four of the women had received some college training. Only 4 per cent of the men were unemployed, 11 per cent being employed part time; 86 per cent of the women were employed in housework and 5 per cent had part-time work.

THE commonest leisure activities of this group were reading, card playing, chess and other games and listening to radio. Outdoor activities ranked next, and were preferred by the men, followed by household activities and then hobbies and outdoor sports. 56 per cent of the men and 48 per cent of the women had two hours or less per day of leisure, but about one half had three hours or more. Only 5 per cent of them did no reading each day, but books were read much less regularly than magazines and newspapers. 65 per cent of the men engaged in farming were members of some organization, but three quarters of the others were members of no formal organization. Emphasis was placed upon the provision for social and recreational needs. 28 per cent of the men and 45 per cent of the women wished to travel, but the only other desire expressed by a significant number was to buy or build a home or to own a good farm. The men would welcome opportunity for further training in agriculture and farming, engineering and mechanics. The women emphasized the desirability of training in business subjects, nursing and home economics. Uppermost in the problems of these young persons is the lack of sociability through group relations, and the major need is that of integrating them into a satisfying social life through the development of a consciousness of common social needs and practical local organization to satisfy them.

River Survey

IN a small pamphlet of a dozen pages ("A Note of the Work of River Flow Records." River Flow Records. 6*d*.), Capt. W. N. McClean sets out a statement of the work performed by River Flow Records, the private organization of which he is the founder and director, during the period of its existence. The aim of River Flow Records, it is stated, is to obtain, in the area of a river system, records of water-levels of so comprehensive and accurate a character as to enable full information to be deduced therefrom respecting the flow and storage of water. Surveys on these lines have been carried out on the Rivers Garry, Moriston, Foyers, Oich and Ness in the Ness Basin; on the River Arkaig and Muccomer Cut in the Lochy Basin; on the River Spey and on the Aberdeenshire Dee, with results which have been detailed in a series of papers and publications. The pamphlet goes on to discuss several aspects of survey work, including water level stations, flow gauging, rainfall, temperature and wind, the compilation and presentation of records and the analysis and use of records. The author points out the influence of the work and experience gained by River Flow Records in the promotion and institution of an Inland Water Survey for Great Britain, which has been the outcome of a discussion in 1932 at the York meeting of the British Association. There are two appendixes dealing with mechanical details of river survey work.

Herpetologia

THE Chicago Academy of Sciences has sponsored the appearance of a new magazine with the above title, to be devoted to the study of reptiles and amphibians. Parts will appear quarterly, and it is hoped that the issue of such a specialized journal will help to bring together notes and short papers upon reptiles and amphibians which otherwise would be scattered and often unavailable in a multitude of other publications. The defect of such schemes is that they tend to make their particular study more remote from the naturalist who is interested in various groups of animals and endeavours to correlate the biological discoveries in them. From such a general point of view, the most interesting of the papers in the first part of the new magazine is that by L. M. Klauber describing and illustrating two varieties of a king snake, one with ringed markings, the other with longitudinal stripes. These have hitherto been regarded as distinct species, *Lampropeltis californiæ* and *L. getulus boylii*, but the hatching of broods which contained both forms shows that they are colour varieties of one form, which must be known as *L. getulus californiæ*.

Seismology in the United States

A REPORT of the Advisory Committee on Seismology appears in the Yearbook for 1935 (pp. 361–370) of the Carnegie Institution of Washington. One of the most interesting sections deals with the operations of the Coast and Geodetic Survey during the year ending June 30, 1935. Levelling of the first and second order was carried out over routes with a total length of more than one hundred thousand miles, and triangulation of the first and second order over a length of about 17,500 miles. In California, three arcs of triangulation, altogether 300 miles in length, have been carried out, and eight lines of closely-spaced bench-marks at right angles to well-known and active faults in the State. Five of these lines cross the San Andreas fault, the movements along which are responsible for many great Californian earthquakes. Each line extends about five miles on both sides of the faults, the bench marks within the first mile being only 100 ft. apart. A short time ago, a network of levels was established in order to study the subsidence of the land round San Jose (Cal.). The levelling was repeated in the autumn of 1934 and the spring of 1935. Though the work is not yet finished, it is advanced far enough to show that the subsidence noticed in the previous interval of levelling is still continuing.

Mining in South Australia

WE have received from the Department of Mines in South Australia the mining review for the half-year ended December 31, 1935 (No. 63). It is quite in the usual form; the main matter of interest is contained in the preface, signed by the Director of Mines on April 1, 1936, in which he states that during the year 1935, the mineral production from South Australian mines and quarries exceeded in value that recorded for any previous year; the total value is 45·4 per cent higher than that recorded for 1934, which was previously the largest total. "The increase in tonnage and in value is due largely to the extraordinary rise in the production of iron ore, which has been the predominant contributor to the total during recent years." This is scarcely surprising since the value of the iron ore raised in 1934 is 84 per cent of the total value of mineral production, the output showing an increase of 50 per cent; most other minerals showed increases, the output of gold being 6·7 per cent greater than that of 1934. These statements are fairly well borne out by the reports of the Chief Inspector of Mines and the reports of the Inspector of Mines and Quarries attached as usual to this volume.

Scientific Study of Suicide

A COMMITTEE for the study of suicide consisting of ten members including Dr. Henry E. Sigerist, professor of the history of medicine at Johns Hopkins University, and Dr. Edward Sapir, professor of anthropology at Yale University, has recently been incorporated to make a comprehensive study of suicide as a social and psychological phenomenon. The following general outline has been adopted by the Committee: (1) intramural studies of individuals inclined to suicide in selected hospitals for mental diseases; (2) extramural studies of ambulatory cases with suicidal trends or with obsessional wishes for their own death; (3) social studies of suicide; (4) ethnological studies, that is, comprehensive investigation of suicide among primitive races; (5) historical studies.

Ministry of Agriculture Leaflets

FOUR advisory leaflets have recently been rewritten for the Ministry of Agriculture and Fisheries. No. 267, which replaces the former Leaflet No. 296, deals with "Potato Growing in Allotments and Gardens". The section on autumn preparation of soil directs attention to the importance of taking precautions against wireworms and leather jackets. It is not now recommended that seed be saved from a previous crop grown in the same district, owing to the depredations of virus disease, and the account of manuring is also brought into line with modern research. Advisory Leaflets No. 180, on "The Cultivation of Raspberries", and No. 268, on "Plums and Damsons", are revised mainly in the sections dealing with soils, diseases and manuring. The fourth Leaflet, No. 113, portrays, briefly, but with businesslike adequacy, modern methods of chicken rearing. The descriptions of sanitary considerations reflect modern research findings upon avian disease, the merits of the various systems of hovers and battery brooders are discussed, and the very considerable advances recently made in our knowledge of the food requirements of poultry are very evident in the section on feeding.

World Power Conference

IN accordance with the constitution of the World Power Conference, which states that the country in which a plenary meeting is held shall appoint the president, Mr. William F. Durand, chairman of the Third World Power Conference, has been appointed to serve until the next plenary meeting. Sir Harold Hartley has been re-elected chairman of the International Executive Council to hold office until the next plenary meeting, and the following have been elected vice-chairmen, to hold office for three years: *First Vice-Chairman:* Mr. O. C. Merrill (U.S.A.), director of the Third World Power Conference; *Second Vice-Chairman:* Mr. G. J. T. Bakker, president of the Royal Netherlands Institute of Engineers; *Third Vice-Chairman:* Dr. M. Kamo, professor in the Faculty of Engineering, Tokyo Imperial University. The Second Chemical Engineering Congress will be held in Berlin in 1940, by invitation of the German National Committee.

Books on Zoology

SEVERAL catalogues of books and periodicals dealing with aspects of biological science have recently appeared. Bernard Quaritch's general catalogue (No. 521) lists all classes of zoological works, to the number of 965. The most complete section is that dealing with entomology, in which is included a selection of books from the library of the late Robert Adkin. Another of Quaritch's catalogues (No. 524) contains two sections of books on early medicine and surgery, and on early science, in all 83 volumes, most of them belonging to the sixteenth, seventeenth and early eighteenth centuries. Messrs. Wheldon and Wesley's catalogue of books on ornithology (N.S. No. 43) is a useful bibliography of birds, listing 1,289 items, the majority of which are arranged geographically.

The Night Sky in October

BETWEEN October 1 and 31, the days shorten by 1^h 48^m in the southernmost part of the British Isles and by 2^h 47^m in the northernmost part. British Summer Time ends on Oct. 4^d 2^h U.T. The moon is new on Oct. 15^d $10{\cdot}3^h$, and full (the Hunter's Moon) on Oct. 30^d $6{\cdot}0^h$. Of the lunar occultations visible from Greenwich, the following may be noted: υ Tauri (mag. 4.4) on Oct. 4^d 20^h $43{\cdot}7^m$ as a re-appearance: τ Tauri (mag. 4·3) on Oct. 5^d 3^h $2{\cdot}8^m$ as a disappearance and its subsequent re-appearance at 3^h 44^m: A Tauri (mag. 4·5) on Oct. 31^d 21^h $56{\cdot}9^m$ as a disappearance and at 22^h $55{\cdot}7^m$ as a reappearance of the star. The planets visible during October are as follows: Mercury as a morning star at greatest west elongation on October 16: Venus as an evening star in gibbous phase; Jupiter as an evening star. Saturn is visible throughout the night; its ring system appears nearly closed, the minor axis being about $2''$. The apparent paths of Uranus (stellar magnitude at opposition 6·0) and Neptune (mag. 7·7) are given in graphical form in the "Handbook" of the British Astronomical Association for 1936. On October 31, Uranus is in opposition, when its distance from the earth will be about 1,745 millions of miles. Mars is in conjunction with Neptune on October 25, when the former planet will be only

0·4° north of the latter. The light variations of Algol (R.A. $3^h\ 4^m$: Dec. 40° 43′ N.) may be observed at about the following times, which represent approximately the mid-epoch of diminished light: Oct. $1^d\ 19^h$, $16^d\ 3^h$, $19^d\ 0^h$, $21^d\ 21^h$ and $24^d\ 18^h$. A nova of the 8th magnitude at discovery on September 18 has been reported from Copenhagen, the discoverer being Mr. N. Tamm of Kvistaberg, Sweden. Its position in Aquila is R.A. $19^h\ 13^m\ 59{\cdot}5^s$: Dec. 1° 36′ 31″ N., not far from the 4th magnitude star, δ Aquilæ. The nova is fading, and on Sept. $23{\cdot}8^d$ was reported by Steavenson as being of magnitude 8·8. The comet discovered on September 20 by Mr. C. Jackson at the Union Observatory, Johannesburg, is in Aquarius, but it is very faint, and invisible except to large telescopes.

Announcements

It is announced in *The Times* that Convocation of the University of Cape Town has elected General Smuts as Chancellor of the University in succession to the King, who held that office while Prince of Wales but vacated it on his accession.

The Ramsay Memorial Fellowship Trustees have made the following awards of new fellowships for the year 1936–37: Dr. E. D. Hughes, a British fellowship of £300, tenable for two years, Mr. R. R. Gordon, a Glasgow fellowship of £300, tenable for two years, and Dr. D. Porret, a Swiss fellowship of £300, all at University College, London. The Trustees have renewed the following fellowships for a second year: Dr. N. Ando (Japanese fellow), University College, London; Mr. C. S. Lees (British fellow), University of Cambridge; Dr. D. MacGillavry (Netherland fellow), University of Cambridge.

At a recent meeting the Association of German Röntgenologists and Radiologists in Czechoslovakia decided to found a Jaksch Prize on the occasion of the eightieth birthday of its president, Prof. Rudolf Jaksch Wartenhorst, to be awarded annually to young röntgenologists who have distinguished themselves by good scientific work.

The fourth European Congress of Mental Hygiene will be held at the Conference Hall, Ministry of Health, on October 5–8, when the following subjects will be discussed: mental hygiene and the cinema; mental hygiene and the nurse; and mental hygiene and the child from eleven to eighteen years. A reception will be given by the Government at Lancaster House on October 5 or 6, and visits will be paid on October 7 and 8 to various psychiatric hospitals, clinics and colonies. The official languages of the Congress will be English, French and German. Further information can be obtained from the Secretary, National Council for Mental Hygiene, Chandos House, Palmer Street, London, S.W.1.

In view of the many requests that have been received from those who attended the conference on mechanization in agriculture held in Oxford last January, it has been decided to hold a second conference at Rhodes House, Oxford, on January 5–8, 1937. A detailed programme will be sent in due course on application to the Conference Secretary, Institute for Research in Agricultural Engineering, Parks Road, Oxford.

Owing to the present condition of affairs in Spain, the third International Congress of Malaria, which was to have been held at Madrid on October 12, has been postponed, but it is hoped that it will take place in the spring or summer of 1937.

The sixth Italian Congress of Microbiology will be held at Milan in April 1937. Further information can be obtained from the secretariat, Via Darwin 20, Milan, 124.

Messrs. Francis Edwards, Ltd., have issued a useful catalogue on Africana (No. 602), which contains a long classified list including several scarce volumes and also a number of autograph letters of David Livingstone referring to his African work.

Applications are invited for the following appointments, on or before the dates mentioned:

A civil engineer and a mechanical engineer in the War Department—Under-Secretary of State (C.5), War Office, S.W.1, quoting "O.P." (October 7).

A lecturer in metal mining in the University of Birmingham—The Secretary (October 9).

A lecturer in electrical engineering at the County Technical College, Worksop—The Principal (October 10).

A male assistant (Grade II) for radio work in a Government establishment in the south of England—Secretary, Royal Engineer and Signals Board, Regent's Park Barracks, Albany Street, London, N.W.1 (October 17).

Temporary assistants (Grade III) at the Royal Aircraft Establishment, South Farnborough, Hants, for ballistic calculations—Chief Superintendent, quoting "No. A.233" (October 12).

A professor in ship design and shipbuilding at the Royal Technical College, Copenhagen—The King, Ministry of Education, Copenhagen, K (October 22).

A regius professor of pathology in the University of Aberdeen—Private Secretary, Scottish Office, Whitehall, S.W.1 (October 31).

A skilled scientific instrument maker at University College, Exeter—The Registrar.

Temporary heating assistants in the drawing office of the Works and Buildings Directorate, Air Ministry—The Secretary (W.B. 9), Air Ministry, Adastral House, Kingsway, W.C.2, by postcard.

Temporary assistants in the drawing office, Civil Engineer-in-Chief's Department, Admiralty—Civil Engineer-in-Chief, Admiralty, S.W.1, marked "Temporary Eng. Assts."

Unestablished assistants in the drawing offices at the Admiralty and H.M. Dockyards—Civil Engineer-in-Chief, Admiralty, S.W.1, marked "Grade III".

An examiner in the Aeronautical Inspection Directorate (A.I.D.) Test House, Cardington, Beds. (metallic materials section, micrographic subsection)—Secretary (S.2.d.), Air Ministry, Adastral House, Kingsway, W.C.2.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 591.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Newton's Prism in the British Museum

A GLASS prism, said to have been the property of Isaac Newton, is on exhibition in the British Museum, Medieval Collections Room, Bay XVI. It was presented in 1927 by the Rev. H. T. Inman of Grantham, a collateral descendant of Newton, and resembles quite closely the prism seen in the hand of the statue of Newton in the ante-chapel of Trinity College, Cambridge. A question which naturally occurs to men of science who see this prism is whether it is one of those which Newton used in his famous experiments on the spectrum in 1666, described in his "Optical Lectures" of 1669, pp. 58 and 75, and reported also in *Phil. Trans.*, 6, 3075 (1671).

Since Newton gave fairly explicit data on the refracting angle and index of refraction of the principal prism which he used on this notable occasion, the question of the association of the British Museum prism with Newton's early experiments might lend itself to a ready answer. Newton states, in the course of the aforementioned references, that the prism which he principally used had as its greatest angle 63° 12′ and that its index of refraction for that portion of the spectrum "tending toward the middle of the green" was 17/11 (1·545).

This question had apparently not been explored until it was recently raised by me in a letter to NATURE. The letter was referred to the British Museum authorities, whereupon Mr. N. J. Plenderleith, head of the Research Department, caused measurements to be made upon the prism which had suggested the inquiry. The report, from which I am permitted to quote, contains the following statements :

"... the characteristics differ markedly from those given by Newton in his paper (*Phil. Trans.*, 1671, Vol. 6, p. 3077).

	Newton's Famous Prism	B.M. Prism
Prism Angle	63° 12′ (max.)	60° ± ½°
Refractive Index (middle of the green)	1·545	1·5933 (5461)

The specific gravity of the B.M. prism is 3·36. . . . The final conclusion is that the prism mentioned by Newton, although undoubtedly a flint glass, cannot possibly be identical with that now preserved by the British Museum."

The question still remains whether or not the British Museum prism is one of those which, though mentioned in Newton's writings, played a less prominent part in his early researches and for which his data are less explicit. It is, possibly, scarcely worth while to investigate this point.

Relationship between Post-Natal Coat Characters and Prenatal Follicle Density as Affected by Increase in Fœtal Size

A SERIES of New Zealand Romney fœtuses have been studied with the view of showing that there is a correlation between post-natal coat characters and pre-natal follicle density as affected by increase in fœtal size.

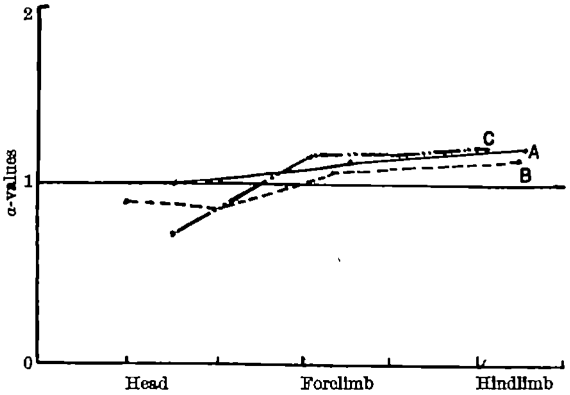

FIG. 1. Antero-posterior gradient in relative growth rate in length (*A*), width (*B*) and height (*C*) at 46–86 days.

It was found from the values of the equilibrium constant[1] α for the different body regions that there exists after the 42nd day stage an antero-posterior gradient in the fœtal relative growth rate for length, height and width. This gradient was slight up to the 80-days stage but was marked from 80 days until 127 days (Figs. 1 and 2).

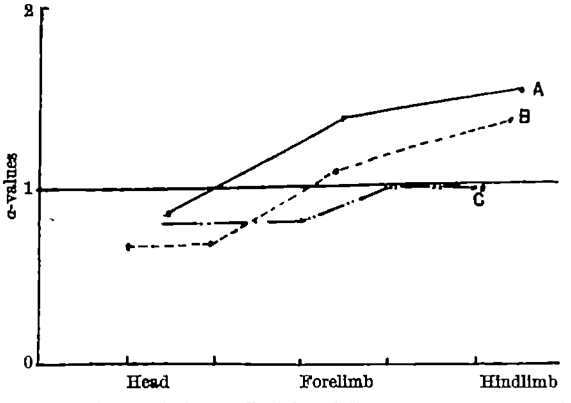

FIG. 2. Antero-posterior gradient in relative growth rate in length (*A*), width (*B*) and height (*C*) at 86–122 days.

This growth gradient was found to be comparable with the britch to poll fibre type array gradient[2] found in the fleece of the lamb. Coarse fibred arrays occurred on regions which grew much more rapidly after the 80th day, that is, after the completion of the trio stage of follicle development[3].

From 'α-with-time' calculations[4] (the curves for which did not vary markedly from the α-curves) it was possible to demonstrate that changes in follicle density regions were associated with changes in the growth rate of that region. Further, from the curves it was shown that on regions with a large number of pre-curly tip fibres—for example, poll and neck regions—follicle initiation commenced when the growth rate of that region was at a maximum.

Full details are contained in my D.Sc. thesis for the University of Edinburgh, and will be published in the form of papers.

Growth Hormones and Development of Plants

LATELY great attention has been paid to vernalization of various agricultural plants. Vernalization essentially consists in retarding the germination of seeds by means of insufficient soaking, low temperature, etc. When afterwards the seeds are subjected to normal conditions, further development of the plants proceeds at a greater rate, flowering and fruiting taking place earlier than in control plants.

The physiological nature of this phenomenon is not yet clear. Some experiments have led me to suggest that vernalization is accompanied by an increase of the concentration of growth hormone in the cells of the embryo[1].

This hypothesis suggested that it would be worth while to soak seeds in concentrated solutions of the growth hormone and examine the effect on the development of the plant. On the basis of previously published data[2] it was to be expected that in this case, at least in the Gramineæ, there would be an accumulation of the hormone in the tissues of the developing embryo.

The following sources of the growth hormone were used for the experiments: a solution of β-indolyl-acetic acid (1–2 mgm. per 10 c.c. water) and also the finely cut and moderately moistened endosperm of maize (without the embryos). The seeds of experimental plants were soaked in these substrates for 24–48 hours at 18°–20° C., and then they were planted out into the soil in flower-pots, and cultivated in a greenhouse. The seeds of the control plants were soaked for the same period of time in distilled water or in moist sawdust.

The most interesting data were obtained in the experiments with oats (Siegeshafer). The plants which developed from seeds 'hormonized' in the endosperm of maize at first lagged behind the control ones in their growth, but later on they were far ahead of them and bloomed twelve days earlier.

From the seeds of oats which were soaked in the β-indolyl-acetic acid, considerably stronger plants developed than from the control ones. Blooming took place simultaneously in both groups. The quantity of grain which was collected from the experimental plants (when calculated per plant) was greater than in the control ones by 55 per cent.

Thus we see that 'hormonization' of the seed before planting sometimes influences the further development of the plants and causes in some cases an acceleration of their development and a shortening of the vegetative period; in other cases a stimulation of growth, accompanied by an increased crop, is observed. It seems possible that treatment of seed by the concentrated solutions of various growth substances may find its application in agriculture.

Divergent Physiological Effects of Synthetic and 'Natural' Ascorbic Acids

DEPENDING upon the concentration of the active substance, the effect of ascorbic acid upon the growth of seedlings may be either stimulatory or inhibitory. It has been noticed before[1,2] that, at a given concentration, the effects of the synthetic product and of the acid crystallized from a natural source were not identical. We have endeavoured to investigate the reason for the discrepancy.

Commercial synthetic ascorbic acid sold by British Drug Houses, Ltd., and the ascorbic acid isolated from paprika and kindly given by Prof. A. Szent-Györgyi, were compared. Pure-line Wilhelmina wheat, which we owe to the kindness of W. H. Parker of Cambridge, was germinated, after external sterilization, on filter paper in Petri dishes. 3–5 ml. of an aqueous solution of ascorbic acid was added daily to the Petri dishes, each containing 30 wheat seeds, aseptic precautions being used throughout. The experiment was concluded after 12–14 days, when the food reserves of the seeds were exhausted. The effects of substances intermediate in the synthesis were also tested. The accompanying table gives our results:

Substance	Concentration	Average length of one shoot (mm.)	Average weight of all shoots (gm.)
Ascorbic acid synthetic	5/1,000	49	0·70
Ascorbic acid natural	5/1,000	72	1·05
Ascorbic acid synthetic	1/1,000	66	1·08
Ascorbic acid natural	1/1,000	97	2·10
d-Glucose	5/1,000	104	1·84
d-Sorbite	5/1,000	80	1·48
l-Sorbose	5/1,000	68	1·25
Water (control)	—	90	1·95

The previously noticed inhibitory effect of natural ascorbic acid at a concentration of 5 in 1,000 has been confirmed. This inhibition is nevertheless much inferior to that produced by the synthetic product of the same concentration.

In previous experiments, natural ascorbic acid was found to exert optimal stimulation at a concentration of 1 in 10,000; from the above results, stimulation by the natural product can be discerned at 1 in 1,000, at which concentration the synthetic substance still shows an inhibitory effect. These remarks do not rest solely upon the measurements cited, but also upon the general behaviour of the seedlings.

As the divergencies of action seemed to point to the presence of some impurity in the synthetic ascorbic acid, we recrystallized it from petrol-ether and methanol. Although incomplete, the results obtained with the material recrystallized from methanol suggest that some impurity was indeed present.

Range of Action of Surface Forces

IN connexion with recent letters under the above heading[1], the following experiments may be of interest.

If two optically plane glass surfaces be worked into close contact, they seize with a force which varies inversely as the square of the distance between the plates[2]. Let rectangular plates be worked to about $1 \cdot 5 \times 10^{-5}$ cm. apart, as shown by the white of Newton's colours of thin plates. The tangential forces of seizure may then be about 100 gm. weight per sq. cm. If now a little water be applied round the edges, it creeps in between the plates, and they are forced apart by increase in the pressure of the trapped air. If the water be applied only at one of the straight edges, it creeps in at a varying rate: for horizontal plates the time t to travel a distance l is proportional to l^2. If, after all air has been forced out, the surplus water be removed from the edges with blotting paper until a narrow Newton-white border is seen all round, it will be found that the plates, with water between, seize with a force much greater than when air is between the plates. A tangential force as great as 1,700 gm. per sq. cm. has, in this way, been found to be borne apparently by a water layer $1 \cdot 5 \times 10^{-5}$ cm. thick.

This is, of course, no proof that the water layer was withstanding this great shear stress, since the glass surfaces were being held apart at the Newton-white distance by 'dirt' props, and since it is possible that the reduction in pressure within the water layer (due to surface tension at its edges) may distort the glass so that the surfaces are closer together in the water than the Newton-white distance observed at the border, and so give greater seizure in accordance with the approximate inverse square law.

It may be of further interest to point out that μ, the coefficient of viscosity of water, can be calculated approximately from its surface tension T, by timing the flow of water into the narrow gap. For a rectangular sheet of water, $\mu \doteqdot TDt/3l^2$, where D is the distance between the plates and t the time to flow in a length l. For a circular capillary tube, diameter d, $\mu \doteqdot Tdt/4l^2$. With a tube 0·036 cm. diameter, an experiment gave a good enough value for μ, namely, 0·010 C.G.S. at 16° C., but with plates about $2 \cdot 5 \times 10^{-5}$ cm. apart, μ came out at 0·11 C.G.S. Whether this high value has to be regarded as a genuine indication of increased viscosity in thin films or as an effect of 'dirt' props and of seizure forces it is hard to say. Sir Joseph Larmor[3] has recalled Kelvin's suggestion that there was experimental evidence of "a new type of intimate friction, entirely different from the smooth viscosity" of hydrodynamic theory.

Constancy of Wave-length of Light

THE recent correspondence in NATURE regarding the constancy of the velocity of light raises the auxiliary question as to the constancy of the wave-length of light. Experimentally, this is best approached by a study of the wave-length of a spectral line.

Mr. James L. Lawson and I continuously observed the 4358 A. line of mercury from June 24 until August 27, 1935, using a Fabry and Perot étalon. The wave-length of this line was found to be constant to within two parts in a million.

While this work was neither so accurate nor so comprehensive as that of R. J. Kennedy, it possessed the advantages of having the interfering beams of light travelling in identical paths and of having been taken at a time when the velocity of light should have been changing rapidly according to Edmundson's empirical law.

More complete information on these observations will soon appear in the *Astrophysical Journal*.

Colloidal Silica in Natural Waters and the 'Silicomolybdate' Colour Test

IN the estimation of silica by the colorimetric method of Diénert and Wandenbulcke[1], the yellow colour produced by the addition of ammonium molybdate in acid solution has hitherto been attributed to the ions of a heteropolyacid. The fact, easy to establish, that silica sols do not, under these conditions, give an intensity of colour proportional to the silica present, has led to the belief that colloid micellæ of silica do not give the reaction, and that the colour intensity is proportional to the crystalloid silica. We believe this view to be incorrect.

We have made colorimetric determinations of the silica content of Nile and certain well-waters, and compared the results with gravimetric data, kindly supplied to us by Dr. W. T. H. Williamson of the Egyptian Ministry of Agriculture. In general, the former results were low. Better agreement was obtained, however, by warming the samples, before test, to 80° C. with a little silica-free caustic soda in a platinum vessel, the amount of acid added being correspondingly increased.

To see whether the colour intensity could be taken as an indication of the content of crystalloid silica, we tested the samples again after passage through Zsigmondy-Bachmann ultra-filters of different grades.

The reduction in the intensity of the colour afterwards produced was found to exceed by far the increase observed on peptizing with caustic soda, and amounted, with a 170-minute ultra-filter, to some 60 per cent. The liquid above the ultra-filter became correspondingly richer in silica as filtration proceeded, and since all sources of error—such as leakage, contamination, or the shifting of the equilibrium between ions and micellæ—would reduce the differences found, it follows that the silica in the waters examined was mainly colloidal. As silica, though a minor constituent of natural waters, is an important constituent of most deposits, this result is of some interest. In our experiments the water samples were filtered through ash-free paper before use, and waxed bottles were used for storage and transport.

Ultra-filtration experiments with the yellow 'silicomolybdate' solutions showed that the latter substance is in a higher state of aggregation than the parent silica, for passage through a relatively coarse 60-minute ultra-filter rendered them nearly colourless. This result raises doubt as to whether the coloured substance is a true heteropolyacid, like those formed by phosphoric and arsenic acids, and suggests that it may be an adsorption complex.

Experiments with a dilute dialysed Graham sol confirmed the above conclusions. The sol, containing 12 mgm. Si/litre, was passed through ultra-filters of different grades, and the molybdate test applied to the filtrates both with and without previous peptization with alkali. The results were as follows :

Ultrafilter	Apparent Si content by usual test (mgm./litre)	Apparent Si content after peptization (mgm./litre)
1 minute	1·8	12
11 minutes	1·1	7·5
63 minutes	<1·0	6·2
200 minutes	Difference indistinguishable and colour barely perceptible.	

It will be noted : (1) that the alkali treatment brought all the silica into reaction, (2) that the finest ultra-filters removed that portion of the silica which reacted without previous peptization, (3) that a 63-minute ultra-filter, though capable of rendering the yellow solution nearly colourless, yet allowed about half the silica to pass through.

With sodium metasilicate solutions, provided they were sufficiently dilute and the molybdate and acid added in sufficient quantity, the apparent silica contents as given by comparison of the colour with the buffered bichromate standards of Swank and Mellon[2] were found to be in fair agreement with the gravimetric determinations. But here also, owing to the addition of the acid necessary for the colour test, the silica which reacts with the molybdate appears to be mainly colloidal : for even with a slightly alkaline solution (pH 8·7, potentiometric determination) a 30 per cent reduction of silica content was effected by passage through a 250-minute ultra-filter.

From diffusion data Jander and Heukeshoven[3] conclude that silicic acid polymerizes rapidly when the pH falls below 10·9. Sea-water, though buffered at very much lower pH values, yet appears to exert a peptizing action, as the following experiment has shown : known volumes of a dilute Graham sol of known silica content were added to silica-poor sea-water, the quantities being such as to correspond to a silica-rich sea-water. Colorimetric tests were then made, both with and without the alkali treatment described. The former tests gave in each case the correct silica content ; the latter gave results ranging from 25 to 100 per cent of this, according to the age of the solution at the time the molybdate was added. We believe, in view of this result, that estimates of the total silica contents of sea-water by the method of Diénert and Wandenbulcke may be not widely in error, provided the silica has been held in solution for a sufficient period.

Fermentation of Phosphogluconic Acid

IN their fundamental researches, Warburg and his co-workers[1] have described in detail the enzymatic oxidation of glucosemonophosphate to phosphogluconic acid. Furthermore, they found that the oxidation product is easily fermented by yeast macerate. Now, phosphogluconic acid might be a first product of carbohydrate oxidation occurring in a manner different from fermentative breakdown. Then the breakdown of phosphogluconic acid effected by yeast extract might represent a further step in the course of oxidation.

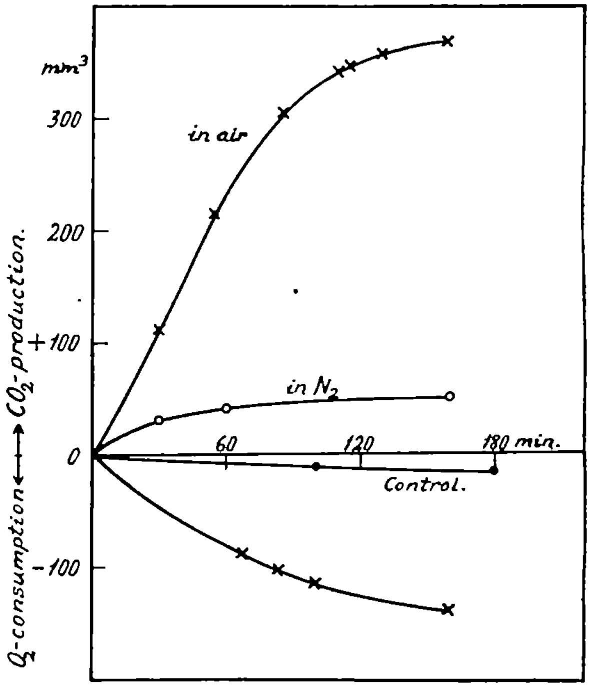

FIG. 1.

Studying this reaction, I found that, in the absence of oxygen, formation of carbon dioxide was very slow. The experiments of Warburg, Christian and Griese[1] mentioned above were done in air. According to my experiments carried out under similar conditions, the rapid formation of carbon dioxide in air was found to be accompanied by an absorption of oxygen ; per oxygen atom absorbed, 1·5–2 mol. of carbon dioxide appeared.

The experiment represented in Fig. 1 shows the ærobic and anærobic fermentation of 0·44 mgm. phosphogluconic acid–P, present in 0·5 c.c. of yeast macerate. The acid was prepared from Robison ester by bromoxidation, after Robison and King[2]. Part of the experiments was done with an almost pure preparation, which was most kindly supplied to me by Prof. R. Robison.

Bromoacetate, in a concentration which would entirely inhibit alcoholic fermentation (0·01 mol.), inactivates only partly. The oxygen consumption is almost unaffected, but carbon dioxide formation is reduced. In this case, per oxygen atom consumed nearly one mol. of carbon dioxide appeared. This might indicate that a primary oxidation and decarboxylation, unaffected by bromoacetate, is followed by a reaction, which may be of fermentative nature. This explanation seems to be corroborated by the experiments of Bernhauer and Görlich[3] on the oxidation of gluconic acid effected by bacteria. They found α-ketogluconic acid as one of the oxidation products. If now in yeast extract phosphogluconic acid is oxidized primarily to phospho-α-ketogluconic acid by one atom of oxygen, this compound, being an α-ketoacid, would easily split off carbon dioxide, giving rise to arabinosephosphate. The quotient $O : CO_2 = 1$, found in the presence of bromoacetate, would thus find its explanation.

Fluoride inhibits both oxygen absorption and carbon dioxide formation somewhat more strongly than bromoacetate.

During the oxidative fermentation of phosphogluconic acid, none or only a small amount of the phosphate is split off.

A New Strigeid Parasite of the Rare Genus *Cyathocotyle*

IN the course of my studies on the avian trematodes of India, a preliminary report on which, dealing with Strigeidæ and Echinostomidæ, has already appeared[1], one complete and one incomplete specimen of a new trematode were found which could not be included in the report above referred to. As the form is very interesting, a brief account of it is furnished here.

Cyathocotyle calvusi n.sp.

Body bulb-shaped, anteriorly swollen, posteriorly narrower; total length 2·06 (all measurements in millimetres on mounted specimens), maximum breadth 1·02, breadth of narrower region 0·038. Oral sucker 0·15 × 0·19, ovoidal or circular, subterminal; pharynx 0·09 × 0·097, nearly globular; cæca simple to near posterior end, broadly arched in front; œsophagus and prepharynx absent. Holdfast organ 0·32–0·4 in diameter, centrally located in globular part, outline irregular, overlapped by vitelline follicles along outer margin; wall covered with very peculiar characteristic, hair-like, fibrous outgrowths. Testes very conspicuous, much elongated; anterior 0·56 × 0·18, alongside holdfast organ; posterior 0·65 × 0·18, in narrower part of body, separated from the hind end by about half its length. Ovary roundish, 0·28 in diameter, masked by vitelline follicles, antero-lateral to hind testis. Vitellaria grouped in large follicles of irregular shape, along intestinal cæca meeting in front. Cirrus sac 0·60 × 0·14, about one-third as long as body, posteriorly drawn out into a long neck; contains coiled seminal vesicle, surrounded by prostatic cells in anterior half, and a long tubular, eversible cirrus in its posterior half. Genital atrium short, with male and female ducts opening side by side into it; genital pore postero-terminal. Eggs about twice as long as thick, not many, 0·081–0·092 × 0·042–0·047. In intestine of King vulture, *Torgos calvus* (Scopoli), United Provinces.

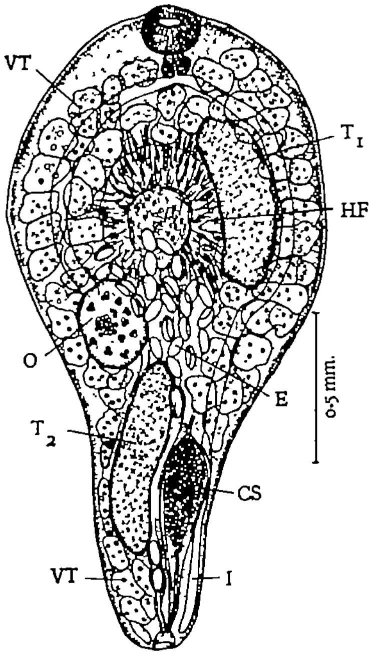

FIG. 1. *Cyathocotyle calvusi* n.sp. View of entire specimen.

Of the known species of the genus, the above worm is the largest, and stands somewhat close to *C. orientalis* Faust, 1921. But in addition to its larger size, it differs from it as well as from *C. prussica* Muehling, and *C. melanittæ* Yamaguti, in its body shape, in its much longer and differently placed testes, in the differing proportion of its cirrus to body length and in size and position of ovary and size of eggs. It would appear to be new to science.

Occurrence of Haploid Pollen Mother Cells in a *vulgare* Wheat

HAPLOID plants have been found in many species, but, so far as I am aware, there has been no recorded instance of haploid pollen mother cells occurring in a diploid plant. Bridges[1] has found patches of haploid tissue in *Drosophila*.

During an examination of smear preparations of the meiotic chromosomes in a seventh generation *H*44 × Reward wheat plant (*H*44 is a *vulgare* selection from the cross Yaroslav Emmer × Marquis), two 'haploid' pollen mother cells were found. One cell contained seven ring bivalents and seven univalents;

the other cell, one heteromorphic trivalent, one heteromorphic bivalent, one open bivalent, five ring bivalents and six univalents.

Apart from these two cells, each having a total of 21 chromosomes, all the other (320) cells on the slide appeared to have the normal number, 42, or thereabouts. The two cells (if none was lost) probably arose through pre-meiotic reduction. If such be the case, the pairing behaviour of the members of the genoms in the two cells is, to say the least, unexpected. Gaines and Aase[2] reported the occurrence of 0–3 bivalents in their *vulgare* wheat haploid, and Yamazaki[3] 0–4 bivalents and the occasional trivalent in his *vulgare* wheat haploid.

Dr. Lillian Hollingshead[4] mentioned the rare occurrence of aneuploid pollen mother cells in *vulgare* wheat hybrids, recording "clear instances of one bivalent and seven univalents, three bivalents and ten univalents, five bivalents and eight univalents, and eight bivalents and eight univalents". Such aneuploid cells could arise secondarily from pre-meiotic reduced cells such as are reported above.

The $M_{IV,V}$-Absorption Edges of Protactinium (At. No. 91)

PROF. HAHN has put at our disposal a quantity of a protactinium preparation, which he has separated from Jàchymov pitchblende residues.

A spectrogram of the M_V-absorption edge of protactinium, showing clear secondary fine structure, is reproduced herewith. This structure has not been observed in the M-series hitherto. It has been obtained with the ionic tube for low tension[1] in connexion with the focusing method[2]. We have measured the M_V edge in the second order with reference to tungsten M-lines and obtained the values:

$$\lambda = 3601 \text{ X.U.} \quad \nu/R = 253{\cdot}1 \quad \sqrt{\nu/R} = 15{\cdot}91.$$

For the fine structure we find the following energy differences from the main edge:

(11) 16 35 51 76 volts.

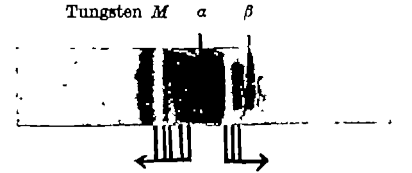
In the position where the M_{IV} edge might be expected, we find an edge with similar fine structure to that of M_V, for which we have obtained:

$$\lambda = 3429 \text{ X.U.} \quad \nu/R = 265{\cdot}8 \quad \sqrt{\nu/R} = 16{\cdot}30.$$

The energy differences of the fine structure edges are:

5·4 17·5 23 36 volts.

By comparing the measured value $\nu/R = 265{\cdot}8$ with that interpolated for M_{IV} of the elements of atomic number 90 and 92, which is $\nu/R = 265{\cdot}1$, it appears, however, that there is a slight difference between them. This variance might have been caused by the fact that at the same position there appears also the K-absorption edge of potassium from the compound (K_2PaF_7). But we have not been able to find any trace of the edge precisely in the position of the interpolated value for M_{IV} and also we are unable, even after observing several spectrograms, to differentiate one from the other. So we are not in a position to decide whether this fine structure is of the M_{IV}-edge of protactinium or that of the K-edge of potassium.



Tungsten M α β
Protactinium M_V obs.
Protactinium M_{IV} obs. + potassium K obs.

FIG 1.

If we now compare the measured values of the M_V-edge with those calculated from the values, $M_V = L_{III} - L\alpha_1$, we obtain the following results[3]:

At. No.	M_V edge (measured)	M_V edge (calculated)	Diff. (meas.—cal.)
92	261·0	261·3	−0·3
91	253·1	253 6	−0·5
90	244·8	245·0	−0·2

From these results it can be seen that, within the limits of observation, there is no difference between the measured and the calculated energy values.

It has been shown[4] that there exists a systematic difference, which is about ν/R meas. $-\ \nu/R$ cal. $= +3$, between the directly measured energy values of the M_V and M_{IV}-edges of the elements from atomic number 83 downwards and their corresponding values calculated from the L-edges. But as our results testify, such a difference does not exist in the case of the highest three elements. It can also be shown from the above results that the same fact is valid for the M_{IV}-edges of the highest three elements.

Research and Teaching in Universities

I CANNOT pass unchallenged the remark quoted from Dr. R. Coulborn's article in the *Nineteenth Century* of July in NATURE of August 22 (p. 304), namely, "the numbing influence of research upon character". This is surely not only untrue but also dangerous. In my experience, the contact with a research problem has proved to be a fine training for a young man, as it provides just the stimulus needed to convert his mind from the text-book outlook upon life to the realities. If it be 'numbing' to teach him proper humility and the scope of his actual knowledge, then let us have more of such refrigeration. Of course, he is not so likely to deal comfortably in future with the vague and foggy generalities which so often pass for a wide humanistic outlook. Any professionalism is narrowing in the wrong hands.

Surely few things are better for redressing the dangers of specialization in research than teaching. It is true that some teachers are bad research workers, and some research workers bad exponents ; but it is my opinion that we do not want now a further separation of teaching and research ; rather we should encourage our leaders of the future to aim at the higher ideal of serving both with efficiency. It is the harder path ; but it could be made more possible if university and other authorities were reasonable in their teaching demands, and relieved their men of the really soul-destroying work, the endless board meetings and administrative checks.

By the above, I do not mean that encouragement should not be given to the development of the research institute under the right direction ; but I think that sufficient research funds should also be in the *independent* hands of universities in Great Britain. This would enable them to support adequately by efficient technical assistance and otherwise their own research enterprises, which so will form a nursery for new ideas and the kind of lively stimulus required by the rising generation.

The 'Specific Action' of Ultra Short Wireless Waves

IN a recent issue of NATURE[1] there appeared a criticism by Prof. W. E. Curtis, Dr. F. Dickens and Mr. S. F. Evans of this topic. These authors mention experiments on tumour metabolism *in vitro* and state that the results claimed by Dr. Reiter[2] are due to heat, adequate precautions against this not having been taken by him. One of us had already come to the same conclusion and published[3] his results on the growth of rat tumours *in vivo*. Furthermore, in a subsequent paper[4] he had shown that there is no sudden change in dielectric constant of tumour tissue at 3·4 m. as might be expected if Dr. Reiter's observations were correct.

We had further shown and published[5] the fact that the frog heart, cilia and muscle, when exposed in a field of ultra high frequency, are affected only when the temperature rose to that level which is known to cause arrest of physiological action.

Points from Foregoing Letters

MEASUREMENTS of the refractive index and the angle of a glass prism on exhibition in the British Museum, said to have been the property of Isaac Newton, show that, while it may have belonged to him, it is not the one to which he referred in connexion with his famous experiments on the spectrum.

The coat characters of New Zealand Romney sheep in relation to the density of hair follicles on different parts of the fœtus at various stages of growth are discussed by Dr. Nancy Galpin, who states that changes in follicle density in a given region are associated with changes in growth-rate.

Oats soaked in a solution of a growth promoting substance previous to planting produced stronger plants and 55 per cent more grain than untreated seeds, according to Prof. N. G. Cholodny.

From experiments on wheat seedlings it appears that natural ascorbic acid (vitamin C extracted from paprika) exerts an optimal stimulation of growth at a concentration of 1 : 10,000. László Havas and Imre Gál report that the beneficial effect is still observed at a concentration of 1 : 1,000, but when the concentration is increased to 1 : 200 there is an inhibitory effect. With synthetic ascorbic acid the inhibitory effect appears at a concentration of 1 : 1,000, and the authors believe that it is due to an impurity.

Experiments are reported by Dr. J. M. Macaulay which show that, if water is allowed to creep in from one edge of a rectangular glass plate which is held by seizure forces to another glass plate distant from it $1\cdot5\times10^{-5}$ cm., the shear strength of the interspace is increased from about 100 gm. to 1,700 gm. per sq. cm., provided there is no surplus water round the edges. By observing the time for the water to creep in between plates ($2\cdot5\times10^{-5}$ cm. apart), a value for the coefficient of viscosity of the water film is calculated and found to be about ten times the normal value for water.

In connexion with the problem of the constancy of the velocity of light, G. C. Omer, jun. and J. L. Lawson have kept under observation for four weeks the mercury line of wave-length 4358 A., and found it constant within two parts per million.

It has been stated that in the colorimetric determination of silica with ammonium molybdate in acid solution, only the molecularly disperse ('crystalloid') silica reacts. From experiments with silica sols which have been ultra-filtered, treated with alkali, etc., Dr. A. R. Tourky and Prof. D. H. Bangham conclude that the silica which reacts with the molybdate is mainly colloidal. The reaction, however, gives approximately correct results provided the silica has been held in solution for a sufficient period.

Graphs showing the rate of oxidation of phosphogluconic acid (in yeast macerate), in presence and in absence of oxygen, are given by F. Lipmann. In the absence of oxygen the formation of carbon dioxide is very slow. The behaviour in presence of bromoacetate suggests that a primary oxidation and decarboxylation is followed by a reaction which may be of a fermentative nature.

Dr. R. M. Love records the occurrence of two haploid pollen mother cells, amongst some 320 normal diploid cells, obtained from one flower of a seventh generation hybrid wheat, which suggests that reduction of chromosome number has occurred in the division preceding normal meiosis.

Research Items

Early Iron in Egypt

MR. CHRISTOPHER HAWKES contributes to *Antiquity* of September a note on the content of two pieces of iron, one from the Great Pyramid (Fourth Dynasty, *c.* 2900 B.C.) and one from Abydos (Sixth Dynasty, *c.* 2500 B.C.), constituting the two major items of evidence for the use of iron in Egypt before the New Kingdom, to which Mr. G. A. Wainwright referred in his article "The Coming of Iron" in *Antiquity* of March last (see NATURE, **137**, 584). It has been shown, Mr. Hawkes now points out, by tests made by Dr. H. J. Plenderleith in the British Museum laboratory in 1926 and repeated in 1932, that the Pyramid piece affords no trace of nickel, and that, although minute traces of nickel were present in two samples from the Abydos piece, these are in samples taken from the outer rust, and no nickel appears in the core. Since all meteoric iron known has been found to contain nickel, it is a reasonable inference that neither of these two pieces is of meteoric origin. Even if the date of the Pyramid specimen is doubtful, as some have maintained, though a later origin seems improbable, there can be no question about the piece from Abydos. Further, Mr. Hawkes, on submitting his material and his conclusions to Dr. C. H. Desch, was informed by him that not only was he satisfied with the result, and accepted the view that the nickel in the Abydos samples of rust was in all probability derived from the associated copper, but he also referred to further specimens of early iron "which is certainly not meteoric" lately received by him from sites in Syria and Mesopotamia. Mr. Hawkes is, therefore, of the opinion that these pieces may be taken as evidence for the occasional smelting of terrestrial iron in the Near East as early as the third millennium B.C.

The Food of Australian Birds

IN a series of articles (*Emu*, 24–35) the late A. M. Lea and J. T. Gray present a great mass of data on the food of Australian birds, based on analyses of stomach contents of 1,708 individuals covering 301 bird species. The results are classified into several main groups, such as: insects—destructive, and useful; seeds and vegetable matter; miscellaneous; and shells. Whenever possible, more detailed determinations of food items are given, while in an appendix all non-vegetable foods are classified in some detail, with lists of birds feeding on them. Although no discussion of the results is presented, the data provide ample material for judging the economic status of any given bird, as well as the relative liability of various animal groups to bird attack. In this connexion, a very high percentage of records of Rhynchota and Hymenoptera, both considered well 'protected', is worthy of notice.

Fauna of Sussex

INTERESTING records and comments upon the birds and butterflies of east Sussex, by N. F. Ticehurst, Capt. T. Dannreuther and others, appear in the *Hastings and East Sussex Naturalist* (5, 120, 157, Aug. 1936). Among the former the occurrence of Sykes's wagtail is discussed, and while it appears to be certain that birds with the characteristics of *Motacilla flava beema* have been seen on several occasions and have bred in the area, the suggestion that the colour variety may not be a true geographical race seems a likely one.

Pseudodiaptomus from South America

THREE species of this copepod genus are already known from South America. Mr. Stillman Wright adds a new one and describes the relationships, distribution and habitat of all four ("A Revision of the South American Species of *Pseudodiaptomus*", *Annaes da Academia Brasileira de Sciencias*, Rio de Janeiro, 8, No. 1; 1936). These calanoids are interesting, for the group seems to be in the process of migration from salt to fresh-water; it is widely distributed and some of the species are apparently restricted to small and nearly inaccessible areas; therefore little is known about them. The South American species are found in water of different salinities; thus, as Dahl has previously pointed out, *P. gracilis*, appeared only in the sample farthest from the sea, in practically fresh-water, and was associated with *P. richardi*. The latter species was the only one represented in slightly more saline water, whilst in waters still more saline *P. richardi* was replaced by *P. acutus*, and this in turn disappeared in sea-water. Apparently the new species, *P. marshi*, taken in the estuary of Rio Capibaribe at Recife, Pernambuco, in Bahia de São Marco at São Luiz, Maranbrao and in the estuary of Rio Jagurabe at Aracatz, Ceára, is adapted to somewhat more salty water than *P. richardi*. So far as is known, none of the South American species lives in the sea.

Mosquitoes of the Ethiopian Region

DURING the last twenty-five years or so, knowledge of mosquitoes has increased to a manifold degree—not only with respect to their relations to disease transmission but also as regards their structure and biology. This vast amount of new information is scattered through many periodicals and, in such a form, it obviously lacks co-ordination. The Trustees of the British Museum (Natural History) have, therefore, taken a step to meet this difficulty in deciding to publish a three volume monograph on the mosquitoes of the Ethiopian Region, that is, of African south of the Sahara. Part I of this work appeared in April 1936, and deals with the general ecology of mosquitoes together with the taxonomy of the larvæ belonging to the Culicine series. Its author, Mr. G. H. E. Hopkins, has spent some years in mosquito survey work in Uganda, which well qualifies him for this task. The present contribution, which runs to 250 pp., is profusely illustrated with excellent text-figures showing the chief diagnostic characters of the larvæ of the different species. The study of the morphology and classification of mosquito larvæ has progressed alongside that of the adults. The advantages of such investigations are obvious since they enable rapid determination of species to be made without the labour of rearing them to the perfect insect—a process not always successfully achieved. At the present day, therefore, knowledge of mosquitoes in the larval stage is as important as a proper acquaintance with the adults. Furthermore, an important aspect of mosquito control is eradication of the larvæ, which in its turn is founded upon a thorough knowledge of their specific habits and breeding places. In the present work these aspects of the work are dealt with as adequately as possible. It is stated in the preface that the other two sections of this work are nearing completion and will be issued next year.

Oil Treatment for Uneven Blossoming

THE influence of climatic factors during the winter months on the crop of fruit trees is examined by O. S. H. Reinecke (*J. Pom. and Hort. Sci.*, 14, 2, 164; 1936) with special reference to South African temperature conditions. Data are presented for prunes and pears which show that when the winter maxima temperatures were high, the crop was poor, and conversely, low winter maxima were associated with abundant yields. The critical temperature appears to be near 64·5° F. Certain varieties of peaches, plums, pears and apples subject to high winter temperature and a shortened dormancy period suffer from 'delayed foliation' and a protracted blossoming period which results in fruits of irregular size and also makes pest control very difficult. Successful attempts to induce even blossoming in these conditions by artificial means are described by M. W. Black (*ibid.*, 175). Apple and pear trees sprayed about four weeks before blossoming with raw linseed oil emulsion, seal oil or certain mineral oil emulsions, produced an earlier, more prolific and more even bloom, whilst fewer leaf buds remained dormant, resulting in the formation of more spurs and shoots. Varieties most susceptible to conditions favouring 'delayed foliation' responded most readily, and the response was more marked after abnormal winters conducive to this disorder. The crop of Bon Chrétien pears was considerably increased as a result of the more normal blossoming, fruit quality, especially the storage properties of the fruit, was enhanced, and the bearing capacity of the tree was increased, due to more fruit buds being differentiated on both spurs and shoots. The oil spray treatment promises to be of great value to commercial growers by virtue of its beneficial effects on fruit production and tree growth in general, whilst the insecticidal properties of some of the mineral oils may be utilized simultaneously.

Soviet Arctic Stations

IN recent years the number of Soviet Arctic observatories, as a rule functioning throughout the year, has been steadily increasing, and now they number no less than seventy-seven. In an article on hydrographic surveys along the northern shores of the Soviet Union in the *Polar Record* for July, Prof. J. Schokalsky gives some account of the institution of these stations. The movement began in 1923 with the erection of a station on Matochkin Shar, Novaya Zemlya. There are now 14 stations on the Barents Sea, 26 on the Kara Sea, 19 on the Laptev Sea, 7 on the Eastern Siberian Sea, 6 on the Chukhotsk Sea and 5 on the Bering Sea. Of the total, 5 are magnetic-meteorological observatories, 28 are first-order stations with registering instruments, 24 take eye-readings only and 11 record observations only three times a day. All stations take observations of ice movements and all have radio-telegraphy. At many of the stations high-altitude observations are regularly taken. The Soviet Union has instituted a special school to train observers for these stations. Each observer as a rule spends only one year in an arctic station.

Viscometry

THE demands made by industry in Germany for accurate standardization of technical viscometers has led the Reichsanstalt to construct an absolute viscometer for the determination of the viscosities at different temperatures of a series of mineral oils which change little with time; these can be used for the standardization of industrial viscometers. The apparatus has been described by Drs. S. Erk and A. Schmidt (*Phys. Z.*, July 15). The liquid is forced by air pressure in succession through two capillary tubes of the same diameter, one short and the other long, which connect three metal cylinders of 4–5 cm. diameter, from which vertical glass tubes ascend to serve as manometers. The pressures are read by cathetometer and their differences for the long and short tubes enable the end effects to be eliminated. The apparatus is immersed in a bath at constant temperature with the capillary tubes horizontal. It has been found that carefully selected tubes drawn in the ordinary way have smoother internal surfaces and are more suitable than tubes formed in the plastic state about a mandril. To facilitate change of capillary tubes their connexions to the metal tubes are made by pipe unions which screw against perforated steel spheres cemented to the capillaries close to their ends. The capillaries are calibrated by mercury threads. An accuracy of 0·2 per cent for the viscosity is attained.

A New Insulating Material

WE learn from the September 13 issue of *Helios*, the electrical trade journal published in Leipzig, that the scarcity of raw materials in Germany has stimulated research for home materials having like or similar qualities. This has sometimes led to the discovery of new materials which are not only better but also possess new and valuable qualities. For example, it has occurred quite recently in the case of insulating tubes, for which supplies of cotton and oil varnishes have to be obtained from foreign countries. A new material called 'isyntha' has been developed which constitutes an excellent material for insulating tubes and wires. Tubes made from this material are free from woven layers and seams and are almost perfectly homogeneous. It is fireproof and is not affected by acids or oils. When tested with a suitable oscillating crank gear testing machine it was only after five hours, when more than a million bends had been made, that a crack appeared. Heating to a temperature of 78° C. for a period of 30 days caused no change in the material. Similarly, it withstood immersion in various acids and in a solution of caustic soda without showing any external change or loss of weight. At a temperature of – 18° C. a tube, which had been roved round a cylindrical rod five times its diameter, showed no signs of breakage or splintering. There are many possibilities of usefulness for isyntha tubes in electrical and radio engineering. Wires covered with it are procurable. The material can be stripped off the wires very easily and is puncture-proof for very high voltages.

Cultural and Social Values of Science*

SIR RICHARD GREGORY, BT., F.R.S.

IT is difficult to define 'cultural value'; for there are many different standards by which it is measured. The term is often used to signify acquaintance with classical languages and literature, but a better view is that learning, whether classical or not, is comprised of many parts and that culture is the one indivisible whole made up of them. When science is taught, not as an aid to a vocation, but as part of the training of a modern citizen, it may justly be claimed to have a cultural value. The purpose of scientific study is to discover the truth about all things, including man, his instincts and impulses, his organization in society. The habit of mind developed by this disinterested pursuit may be as effective an ethical agency as that usually associated only with studies of what are called the humanities.

Cultural and social values are, however, rarely implied in the study of science, but with that of literature, history and other subjects believed to be of a more humane type. Even among scientific workers themselves, there are many who are content to regard experimental and observational inquiries as belonging particularly to the natural sciences, and are indifferent to the application of scientific methods to the investigation of social problems or the influence of scientific knowledge upon human thought. Recognition of interrelationships between all departments of learning is, however, becoming more common than it was a generation or so ago: and the forces which were formerly engaged in conflicts between science and religion or science and classics now profess joint interest in the cultivation of all fields of human enlightenment.

Science and literature, or what are called the humanities, are not now regarded by responsible authorities as opposing elements in education. The two terms should be considered as synonymous; for science rightly conceived is modern humanism in the fullest sense. Even if the humanities are understood to mean letters, history and art, there should be no conflict between these studies and natural knowledge.

But though scientific workers know well enough how science touches art and music, how it may enter into literature and how it makes history, there is not like appreciation of science from representatives of those schools of thought and teaching. It cannot be said that the intellectual horizon of men of letters of our own times has been extended by advances in modern science. There is not much evidence in the works of leaders of literature of assimilation of the new knowledge, or even of sympathy with it. Occasionally one finds a reasonable attitude towards the age of science and invention in which we live, but more usually there is an absence of an outlook which will regard science not merely as a storehouse of facts to be used for material purposes, but as one of the great human endowments to be ranked with art and religion and the guide and expression of man's fearless quest for truth.

The influence of science upon material progress and human comfort is understood much more commonly than that of its effect upon the human mind. It is difficult for people of these times to realize the liberation of life and intellect brought about by the works of Copernicus, Galileo, Vesalius and other pioneers of scientific learning. The very foundations of belief were shaken when it was shown that the abode of man was not the centre of the universe but only a minor member of a group of planets revolving around a sun which was itself only one of many thousands of suns in stellar space. When Newton had shown that his law of gravitation was sufficient to account not only for the movements of the planets but also for the paths of the comets, it was no longer reasonable to believe that they were sent as signs or warnings to the human race. Consider the tremendous revolution involved in this substitution of permanent natural law for the conception of a world in which all events were believed to be reflections of the moods of a benign or angry God.

The sense of justice which resulted from the knowledge of the existence and permanence of law in Nature profoundly influenced human thought, and resulted in social changes which had the greatest civilizing effects.

Just as Copernicus deposed the earth from the position it was supposed to occupy in the universe, so Darwin placed man in a new relationship to the rest of living creatures. Science is concerned with the progress of knowledge and the evolution of man not only in the past but also in the present and future. We need not believe that man has degenerated from a state of perfect knowledge to that of being "born in sin and shapen in iniquity", or that the recovery of his lost position must be looked for not in this world but in the next. The adoption of this depressing doctrine is opposed to evolution as a whole and subservient to all progress. Unlike the creatures of the field, man can make his own environment and so promote the development of any type he desires to survive. The social heritage to which he succeeds has an important influence upon his thoughts and conduct, but he himself can exalt or degrade it.

The advance of science in modern times has had supreme social value in the alleviation of human suffering and increase in the capacities and facilities for human happiness. As whatever subjects are defined as cultural or humanistic must be understood as being concerned with the welfare of man, the conquest of disease as the result of scientific research may rightly claim a high place among them.

Progress in physics and chemistry has profoundly altered those social conditions which it is the purpose of social science to study. The immense increase in the productive capacity of mankind is forcing society to consider the human consequences of the unlimited resources now at its disposal.

Scientific methods applied to the fields of politics, human biology, sociology, economics and psychology will enable facts to be ascertained and assembled for consideration by minds free from passion and prejudice, but knowledge of history and insight into human nature will be required to arrive at sound conclusions and construct practicable policies upon them.

---

* From contributions, made in the order here printed, to a discussion in Section L (Educational Science) of the British Association at Blackpool on September 10.

In recent years, leading representatives of science have warned the world of the disastrous consequences which must ensue unless the gap is lessened between scientific advance and moral or ethical development in both national and international spheres. Unless science repudiates the methods of cultivated barbarism involved in modern warfare, it must lose whatever right it now possesses to be a spiritual influence and acknowledge with despair that man's ethical evolution has already reached its culminating point. Such an end cannot, however, be contemplated, and it will be avoided by conserving social and spiritual values with scientific teaching and research. With this unity of intention it will be possible to hope for and expect scientific guidance of human growth not only towards individual fitness but also towards a higher human perfection.

PROF. LANCELOT HOGBEN, F.R.S.

We all know what is meant by the vocational aspect of education, and we wrongly assume that there is equally general agreement about the meaning of its cultural side. In theory, the word cultural commonly covers two entirely different functions of an educational system. One is the private problem of helping the individual to discover for himself or herself congenial sources of enjoyment to occupy leisure in after life with the fullest allowance for variety of temperament. The other is the public business of equipping individuals with the knowledge necessary for the discharge of their mutual responsibilities as co-citizens of a democratic society without regard to the personal inclinations of the child. In practice, what is called cultural education is neither the one nor the other. Good taste, which is synonymous with ostentatious refinement appropriate to a leisured class, takes precedence over the cultivation of individual satisfaction of temperamental needs, while political rationalizations of a bygone age exclude the study of resources for welfare which a modern community can use or abuse.

Increasing specialization and expanding outlets of vocational choice for individuals with a native inclination or aptitude for scientific studies must progressively limit the appeal of science as an active hobby. Meanwhile the demand of popular educational movements like the W.E.A. is for information about the social problems of our time. That science should be taught, because it teaches children to be observant and curious, is a dubious proposition. The case for science as an essential part of the education of the average man or woman does not rest on gratuitous assumptions about the transfer values of particular disciplines, or on the individual satisfaction which a small class of individuals may derive from verbal disquisitions on the latest, least digested discoveries at the periphery of theoretical research. The cultural claims of science rest on the social fact that the use and misuse of science intimately affects the everyday life of every citizen in a modern community.

While it is happily true that educationists are ahead of the scientific specialist in so far as the cultural teaching of science demands emphasis on its place in everyday life, the claims of science in the education of the citizen extend far beyond a passing familiarity with the way in which society at present uses the knowledge available for the advancement of human well-being. What is far more important is a recognition of the potential of human welfare inherent in scientific knowledge, which existing social machinery fails to exploit for the common weal. Even this neglected aspect of the problem which confronts us in designing a general course of science to take its place in the curriculum of humanistic studies does not exhaust all the issues which should claim pre-eminence. Others emerge more clearly, if we consider the dangers with which the preservation of democracy is now faced. One is failure to anticipate the dire penalties we may pay for the misuse of science. Complacent acceptance of its prostitution to destructive ends, and ignorance of the constructive alternatives which existing knowledge places at our disposal, will have disastrous consequences for all of us, if the helplessness and horror of modern war is canalized in a revolt against science, a repudiation of the benefits which science can confer and a retreat to a lower level of civilized living.

In contradistinction to purely static emphasis on the place of science in everyday life to-day, education for citizenship demands a knowledge of how science is misused, how we fail to make the fullest use of science for our social well-being, and, in short, a vision of what human life could be, if we planned all our resources intelligently. It calls for understanding of the way in which social agencies foster new discoveries and their useful application. In addition, it must reinforce confidence in rational endeavour by emphasizing the role of advancing scientific knowledge in the growth of social institutions.

A course of general science adapted to the requirements of citizenship should be orientated towards the elucidation of the major constructive achievements of natural knowledge in the evolution of civilization. Among the cardinal themes which thus replace the arbitrary division of science into separate 'ologies', those which claim special attention are the construction of the calendar, the technique of navigation and map making, the extension of deep-shaft mining and exhaustion of fuel supplies, the introduction of inanimate and mobile power, the discovery of chemical fertilizers and the principles of scientific breeding, the control of epidemic diseases and the national dietetic minimum. School science should not be a selection from the competing claims of specialist disciplines. It should be the story of man's conquest of time reckoning and space measurement, of the search for materials and substitutes, the liberation of natural sources of power and the struggle against hunger and disease. When it becomes this, the theoretical principles which have the greatest yield will emerge far more clearly, and there will be less reason for disagreeing about the relative importance of different aspects of scientific knowledge.

The indifference of men of science and educationists in the universities has relinquished one unique opportunity for implementing the cultural claims of science. It was offered shortly after the late European war, when the Civil Service Commission made a paper on *Everyday Science* compulsory for all candidates at examinations for higher grades. Provision of special instruction for such candidates, mainly drawn from the ranks of graduates who specialize in linguistic and historical disciplines, might have become a nucleus for the training of teachers for general science as a cultural subject. The examination proved to be a farce, presumably because no such provision was made until last year, when the Commissioners took the retrograde, if comprehensible, course of omitting *Everyday Science* from the list of compulsory papers. The only official recognition of the need for scientific knowledge in the administration of the nation's affairs was thus withdrawn. Such decisions are not necessarily irrevocable, and it is still possible to bring the pressure of public opinion to bear on the Civil Service Commission. If it can be persuaded to reconsider the matter, the British Association would perform a useful service by appointing a joint committee of educationists and men of science to draw up a syllabus of instruction, and urge the universities to provide it.

Whether science will take its needful place in the instruction of the citizen and statesman depends far less on the attitude of the scientific specialist than on that of the educationist. The scientific specialist is too much immersed in his work and too much imbued with an attitude of social indifference generated by a long period of comparative prosperity and security to take an active part in the educational reformation which the present crisis in democratic societies calls for. The problems of the post-War world demand nothing short of a transvaluation of all educational values. Over-specialization is one of the great obstacles to their solution. If the educationist is to make a constructive contribution to the social problems of the present time, he will have to forfeit the luxury of false modesty in his dealings with the claims of specialists.

SIR A. D. HALL, K.C.B., F.R.S.

The true aim of science is the enrichment of life. Through science man obtains an increasing control over the operations of Nature and the blind forces which limit his activities.

It is commonplace to enumerate the gifts of science to humanity during the last century, such as the speeding-up and extension of communications by steamboat, railway, motor-car and aeroplane. Science gives us new sources of light and heat in our households, unwonted textiles for our clothing, healthier and more attractive food. Science is minimizing the curse of Adam—manual toil. At one time a man required a week to dig an acre; the horse plough enabled him to do it in little more than a day, the modern tractor will make light of it in an hour.

Such gains may be dismissed as material only, but science has equally contributed to our spiritual enrichment. Consider only the enlargement of our knowledge of the world and of the appreciation of history that easy travel has brought, or the contacts with art that photography has made possible. The gramophone has brought the whole range of music within the reach of the ordinary man. Wireless is contributing to the mark of the educated man—that awareness of what is moving in the minds of men.

Yet only a few years ago in a sermon to the British Association, Bishop Burroughs appealed for a ten years' vacation for science. Science is beginning to take on the aspect of an enemy, frustrating the enjoyment of all the advantages it can offer. Science is regarded as dangerous because at the same time as it is conferring the powers of production, people at large are learning of these powers and beginning to ask why they cannot enjoy their fruits.

Science means power, but it has given no consideration to whom that power should be entrusted and to what ends it should be used. The acceleration of productive power has led to over-production and unemployment; the sudden development of a new invention may throw another town into long-continued distress and poverty. The new developments of war methods by science are putting appalling powers of destruction into the hands of Governments.

The greatest of all dangers lies in the temptation that is now offered to the power-mongers. Once having obtained control of the machinery they can wipe out any further exercise of the popular will. Of old, every autocracy ended in revolution; What chance has a rising to-day against guns and gas? Moreover, a subtler technique has been evolved, not merely to control the people by force but also to subdue their minds until they will to be slaves. We are learning how the robot can be created by a Government controlling the Press and all publications, closing the frontiers to all communications, using the wireless and education as instruments of propaganda. The old reformers fought for universal education; Did they ever consider how it would be used to consolidate a tyranny? It is reported that the Germans are moving towards uniformity by the sterilization of the dissidents. The end is the ant community of soldiers and obedient workers.

Putting aside the fundamental question of whether the fruits of science can be enjoyed by the whole community or only by the few, how far can the knowledge of science be shared? It is a common reproach that people are using science without understanding—they press a button or turn a switch. This is no valid reproach; science is for the specialists, but general science should be the basis of education for all, and in this lies the only hope for the future. The specific value of education on a basis of science is that it will encourage if not create a habit of acting on reason rather than emotion. One may recognize that emotion is the spring of action and yet realize that reason can exercise some control.

Party, Country, Religion—these are the kind of emotional issues which constitute the false money wherewith the politicians buy power. They are all forms of the easiest of self-delusions—that of belonging to a chosen race. Step by step the habit of illusion is built up—the old school tie, the club, the regiment, the social class, the nation. In themselves these loyalties are excellent, their dangerous side is that they breed hatreds of the "lesser breeds without the law". The function of an education based on science is to destroy this illusion and to teach people from their earliest formative years that men and women, however diverse as individuals, yet are, collectively and statistically, very much alike. I maintain that this can be effected by a scientific education rather than a purely literary education. The latter is concerned with the past, it pictures the world as governed by the play of emotions, its effect is generally to induce a desire to reproduce the old world and to discourage any confidence in the accelerated tempo science has brought about.

But even education is not enough; men of science will have to organize to make their point of view prevail. This is alien to the temperaments of the leaders in the world of science. They want to remain in their laboratories and secrete knowledge without bothering about its purpose. To do so is to accept slavery.

Association of Special Libraries and Information Bureaux

ANNUAL CONFERENCE AT OXFORD

THE thirteenth Annual Conference of the Association of Special Libraries and Information Bureaux was held at Balliol College, Oxford, on September 18–21. In an address on September 18, Dr. Cyril Norwood, who has succeeded Sir Richard Gregory as president of the Association, dealing with the question of school libraries, asserted that no one can be regarded as educated who has not learnt how to use a library, and directed attention to the difference between text-book knowledge and that which comes from first-hand reading. No man is well educated until he has read real classics and mastered them, has learnt how to consult authorities and collate and use the results.

This point of view formed the keynote of a discussion on the following morning, which was opened by a symposium of papers on "Library Instruction for University and Research Students in America", presented by Miss Granville Meixell, librarian of the Applied Science Library, Columbia University. The first of these papers was by Dr. Peyton Hurt of the University of California, on "Teaching the Use of Libraries", and emphasized the necessity of giving students at least one course in library methods and general bibliography to provide them with a unified outline of the materials and methods involved in using a library for information on a wide variety of miscellaneous substances on which information might be needed during their lives. Dr. Hurt gave a brief account of the course which has been developed at the University of California, and in a subsequent paper Miss E. M. Witmer, Miss E. M. Feagley and Prof. C. Alexander described the consultation services for teachers and for others which have been organized at Teachers College, Columbia University. A special service for doctoral candidates, for example, includes systematic instruction on the location of educational information and data, methods of educational research, and bibliographic research for special areas in education. A further paper by Mr. Louis Shares, of the George Peabody College for Teachers, outlined a programme of library instruction for teachers which provides instruction in the use of libraries and is supplemented by a course of more detailed training for those becoming full-time school librarians, college librarians, etc. The final paper in the symposium, by Mr. Donald Gilchrist, described the instruction in the use of books which is given at St Stephen's College, Columbia.

The symposium stimulated a vigorous discussion which indicated a fairly strong general opinion that systematic instruction in the use of libraries is badly needed in most of the universities of Great Britain, and that many of the municipal and other libraries take very seriously the task of educating the user in the consultation of books and other sources of information.

At a subsequent session, Mr. J. J. Eaton presented a paper on behalf of Mr. W. H. Johnston of the *Yorkshire Post*, describing the methods by which information is collected for the commercial pages of a great daily newspaper. Colonel L. Newcombe, of the National Central Library, described the compilation of a Union Catalogue by the London Public Libraries Union Catalogue Committee. Although expensive to compile, its value in enabling the staff of the National Central Library and the Regional Bureaux to locate books has fully justified the expense, and without it efficient and economical co-operation is impossible. None of the alternatives provides a satisfactory substitute and most of them are also expensive.

The paper presented by Prof. A. M. Carr-Saunders on the "Need for Centralization of Information on Economic and Social Surveys" provoked a lively discussion. Prof. Carr-Saunders dealt mainly with the local social survey, particularly of the type represented by Booth's "Life and Labour of London", repeated by the work of Rowntree and Bowley and the surveys on the Tyneside, Merseyside and elsewhere. Discussing the conditions under which social surveys might be of value to-day, he urged the need for some central authority to guide and co-ordinate local surveys. Research is not everywhere equally worth while, and the areas where surveys are particularly wanted are those with very definite special problems and those typical of a certain kind of area which has not already been surveyed. In the absence of central guidance, there is no certainty that surveys will be initiated where they are most wanted, as the resources are more likely to be found where social problems are least pressing and surveys least necessary.

In addition, Prof. Carr-Saunders is of opinion that central guidance is required to indicate the main objectives which it is now worth while to pursue and also to accumulate and disseminate information as to the best methods to pursue. As an example of objectives for future surveys, he suggested that it would be of value to re-survey some of the places already examined, so as to obtain an adequate measure of changes in poverty. The functioning of the social services also merits attention, and an investigation of local government and the administration of the social services and of their impact upon the population should yield very valuable results. This suggestion is an example of what Sir Josiah Stamp urged in his presidential address to the British Association, and like Sir Josiah, Prof. Carr-Saunders also urged a more equitable distribution of resources between research in the social sciences and the natural sciences. The former is essentially as costly as the latter.

Good discussions characterized most of the remaining sessions of the Conference. Dr. J. E. Holmstrom's account of a system of card indexing of abstracts and research data developed for a small special field to provide instantaneous reference led to some debate on the value of the Universal Decimal Classification. Mr. B. M. Headicar's criticism of the price of Government publications in his rather disjointed paper on the collection, classification and utilization of these works drew a prompt reply from Lieut.-Col. N. C. Scorgie, Deputy-Controller of H.M. Stationery Office, who presided over the session and pointed out that at the present time the price of Government publications is in fact being steadily reduced.

At the final session of the Conference, a paper and demonstration on "The Film in Industry: the Development of the Documentary Film and its Growing Use in Research and Advertising" was given by Mr. John Grierson, of the G.P.O. Film Unit.

The report presented to the annual conference of the Association referred to the publication of the *ASLIB Book List* of quarterly recommendations of scientific and technical books, which has proved a successful development. The work of the inquiry bureau has increased and has been facilitated by the removal to larger premises. The working of the panel of expert translators is being reviewed by a sub-committee with a view to reorganization. The accounts for the year ended June 30 show a small excess of income over expenditure, and the number of members is 305. The report once more refers to the way in which activities are being hampered by lack of financial resources.

Educational Topics and Events

THE Physical Society announces that the eighth annual Craftsmanship and Draughtsmanship Competition will be held as usual in conjunction with its annual exhibition of scientific instruments and apparatus in January next. Competitors must be in the regular employ of a firm or institution which will be exhibiting or has exhibited at least once during the past three years, and which has been invited by the organizing committee to enter its employees for the competition.

THE London County Council's prospectus of lectures and classes for teachers, 1936–37, "designed to bring London teachers into touch with the latest developments in educational methods, to give them opportunities of hearing leading authorities in various branches of learning and on current questions of importance", offers a very wide range of choice to those prepared to give some evenings to the pursuit of these admirable aims and (for the scheme is self-supporting) to pay the moderate fees charged. Last year the entries exceeded 15,000. Among the outstanding attractions are: courses on physical and mental development of children by Prof. H. A. Harris, professor of anatomy in the University of Cambridge; on the development of the child's personality by Prof. Charlotte Bühler of the University of Vienna, director of the Parents' Association Institute; on the psychology of adolescence by Prof. Cyril Burt; on "everyday physics" (the atmosphere, lighting of streets, preservation of food, photoelectric cells, acoustics, modern buildings, etc.) by C. R. Darling; on the Decroly system by Mdlle. Amélie Hamaide of the Ecole Nouvelle, Ixelles, Belgium; on "electricity in the home" by Mr. J. Paley Yorke; recitals by Miss Jean Sterling Mackinlay to demonstrate how to give songs a dramatic and pictorial value; and single lectures by Mr. Frank Dobson on sculpture, Prof. Walter Gropius on modern architecture, Rosita Forbes on "Through Afghanistan to Russian Samarcand", Prof. P. M. S. Blackett on cosmic rays, Dr. F. A. Freeth of Imperial Chemical Industries, Ltd., on modern developments in chemical industry, Prof. J. B. S. Haldane on heredity, and Sir Frank Smith on wireless waves.

Science News a Century Ago

The Entomological Society

AMONG the matters considered by the Entomological Society at a meeting on October 3, 1836, were a notice from H.R.H. the Duke of Sussex, relative to the injury sustained by the pear-tree, arising from the attack of a small subcutaneous larva, evidently one of the Tincidæ; a memoir by W. Sells on the black caterpillar of the *Athalia centifolia*, one of the saw-flies, which during the past season had caused great devastation upon turnips, and a letter from W. Spence containing additional observations upon the natural history and mode of attack adopted by the *Scolytus destructor* upon the elm trees of France; and proving the necessity of an acquaintance with the precise habits of the insect previous to any wholesale felling of the trees, which, although apparently greatly injured, might not contain a single larva; these observations were supported by various facts which have been noticed by Spence and M. Audouin, professor of entomology at the Jardin des Plantes.—(*Athenæum*.)

Buckland's "Bridgewater Treatise" on Geology

IN a letter written on October 4, 1836, to his father, Lyell said they had just called on the Fittons in Portland Place and had had much talk about the presidency of the Geological Society. Fitton, said Lyell, "told us what Gardner the mapseller has since confirmed that Buckland's edition of 5,000 of the 'Bridgewater' is all sold, and 5,000 more printing, each of which editions, Fitton says, will produce the professor £2,000—a piece of news I am truly glad to hear, for what I have read of the book, I think it will do much good in spreading correct notions of the science, and probably popularise it much. Murchison calls it 'Bridge-over-the-water'; and really that part which is to carry us over the abyss of cosmogony is better constructed than I expected, though I should have been sorry to have had to trust myself upon it. Fitton thinks the moral of it to be, that words may mean anything we like, or that science may require a dangerous rule in its general application."

The Steam Department of the Royal Navy

IN the Public Record Office is preserved an interesting report on the organization of the Steam Department of the Royal Navy, dated October 8, 1836, and signed by Captain Robert Oliver, Lieutenant Thomas Baldock and Master Charles Brown. The name of a steam vessel had first appeared in the official Navy List in 1827, and by 1836 some twenty-six steam vessels were included in the list of H.M. ships. The most important steam vessels were then the *Dee*, *Phoenix*, *Salamander*, *Rhadamanthus* and *Medea*, vessels of about 800 tons and 220 nominal horse power, and it was through experience gained with them that the Admiralty laid down in 1836 the first steam frigates, *Gorgon* and *Cyclops*.

At that time there was no properly organized engineering branch of the Navy, engineers possessed no rank and the manning of the engine-rooms and the working of the machinery gave rise to many questions. The three officers mentioned were therefore appointed to report on the machinery of the steam vessels. Of the three, Captain Robert Oliver had commanded the *Dee* during the blockade of the Dutch coast, while

Lieutenant Baldock had commanded the steamer *Firebrand*, one of the vessels used by the Admiralty for carrying the mails between Falmouth and Malta. To Baldock we also owe a memoir of Her Majesty's Steam Ship the *Medea* during a service of nearly four years.

The London Meteorological Society

WRITING on October 9, 1836, from Wycombe to the editor of the *Analyst* (5, 289), J. G. Tatem directed attention to the value of the study of meteorology, and in the course of his letter said: "It must have been matter for surprise that, while there is scarcely a science or art but receives encouragement and support from a society composed of persons professing the one or attracted to the other, Meteorology does not enjoy that patronage. True it is that, in 1823, a society was established in the metropolis under the denomination of 'the London Meteorological Society', admitting persons residing in the country as corresponding members. Of that society Dr. Birkbeck was the president, Dr. Clutterbuck the treasurer and Mr. Wilford the secretary, with a council consisting of eight members; but it never came into active operation, and soon fell into decay. . . ." It was the aim of Mr. Tatem and others to resuscitate the society so that "Meteorology would be able to boast of having a society as extended and active as any of those which are advancing science in every direction, and conferring so much honour upon the country".

Societies and Academies

Paris

Academy of Sciences, August 24 (*C.R.*, 203, 445–472).

PIERRE AUGUSTIN DANGEARD: Necrological notice on Camille Sauvageau.

GEORGES PERRIER: The Martinique Institut de Physique du Globe.

MIÉCISLAS BIERNACKI: The multivalent functions of p order.

PAUL BOURGEOIS and JACQUES F. COX: The origin of comets. The theory of the galactic origin of cometary matter is in accord with known data.

JEAN DUFAY and HENRI GROUILLER: The proportion of polarized light in the solar corona. After correcting for the width of the slit of the spectrograph and the analysing slit of the microphotometer, it was found that the proportion of polarized light was practically independent of the wave-length in the whole of the spectral region studied. The proportion of polarized light reaches a maximum of 0·26 about 10′ from the edge and this maximum is very flat. This result, obtained for the total eclipse of August 31, 1932, was confirmed by J. J. Johnson during the eclipse of February 14, 1934.

JEAN CHAZY: The approximate calculation of the precession of the equinoxes.

JEAN MARIANI: The law of gravitation and parallel displacement.

RENÉ LUCAS: Absorption of elastic waves in fluids.

NY TSI-ZE and FANG SUN-HUNG: The circular transversal vibration of a hollow quartz cylinder.

EDOUARD ROCH: A zone of irregularities, principally with nuclei of eruptive rocks, in the Haut-Atlas, to the east of Marrakech.

PAUL BERTRAND and PAUL CORSIN: The relative independence of the large groups of vascular plants.

HENRI HÉRISSEY and GABRIEL POIROT: The extraction of a crystallized principle, viburnitol, from the leaves of *Viburnum Tinus*. The fresh leaves give a yield of 0·1 per cent of the substance. Its composition is $C_6H_{12}O_5$; it contains no methoxy group and appears to be a polycyclic alcohol.

JACQUES BENOIT: Hypertrophy of the liver in the thyroidectomized duck. The role of the prehypophysis in its enrichment in lipids.

LÉON VELLUZ: The neutralizing action, *in vitro*, of carbon disulphide on the tetanus toxin.

August 31 (*C.R.*, 203, 473–504).

LOUIS DE BROGLIE: The theory of the photon and the relativist wave mechanics of the systems.

LUCIEN CAYEUX: The microplankton of the Tunis and east Algerian phosphates.

VITO VOLTERRA: Vital least action.

JACQUES DE LAPPARENT: Relation of the bodies of the sepiolite-attapulgite series with the phyllitous silicates of the mica type.

JEAN CABANNES and HUBERT GARRIGUE: A photoluminescence phenomenon in the upper atmosphere: stimulation by solar light of the oxygen line 6300 A.

N. A. SLIOSKINE: The theory of the plane movement of a viscous liquid.

JACQUES VALENSI: Aeroplane wings: the influence of the form of the end of the wing on the marginal phenomena.

ROBERT LACAU: The liberation of a yellow oil in mixtures of tar and bitumen.

G. ZBYSZEWSKI: The extension of pre-Devonian strata to the middle of the eruptive series of Beja (Portugal).

RAYMOND FURON: First results of a geological exploration of the great Iranian desert.

MAURICE ROSE and HENRI BERRIER: The topographical distribution of substances functioning as plant auxins in the young tadpole of *Discoglossus pictus*.

LÉON VELLUZ: The neutralizing action, *in vitro*, of the senevols on the tetanus toxin.

GEORGES BOURGUIGNON and MLLE. RENÉE DÉJEAN: The variations of vestibular chronaxy in hemiplegia with or without aphasia.

CHARLES FLANDIN, PIERRE BARANGER and JEAN RAGU: An attempt at the treatment of leprosy with a new complex compound of chaulmoogra and cholesterol, allowing the intravenous injection of large doses of chaulmoogric derivatives. Description of favourable results obtained by this treatment in twelve cases.

Cape Town

Royal Society of South Africa, June 17.

E. NEWBERY: Mercurous perchlorate and the monovalent mercurous ion.

C. VAN RIET LOWE: Rock engravings in the Vaal River basin. A description of rock-engravings recently discovered in the Vaal River basin, giving their relative chronology, and associating certain early phases with implements of the Smithfield *A* and *B* series.

L. N. COHEN: Studies in the inorganic metabolism of the Kelsey and Gaviota plums (1). Potassium.

Rome

Royal National Academy of the Lincei
(*Atti*, 23, 253–276; 1936).

U. Cisotti: Ballast effects due to a doublet.

G. Scorza-Dragoni: Doubly periodic planar translations of Brouwer.

A. Ghizetti: Determination of the limiting curves of a continuous ∞^1 system of homographic plane curves.

G. Bernardini and **O. Bocciarelli**: Valve instrument for registering coincidences between multiplying counters.

G. Dal Piaz: Geological structure of the Austrides (2). The Austrian alpine system south of the tectonic window of the High Taurus.

V. Puntoni: Relations between the anærobic actinomycetes of the Wolff-Israel type and *Bacterium bifidum*.

Washington, D.C.

National Academy of Sciences (*Proc.*, 22, 435–462, July 15).

Aurel Wintner: On the periodic analytic continuations of the circular orbits in the restricted problem of three bodies.

A. E. Mirsky and **Linus Pauling**: On the structure of native, denatured and coagulated proteins. Discussing proteins from the point of view of their physical and chemical behaviour, it is concluded that the molecule consists of one polypeptide chain (sometimes two or more) which continues throughout the molecule. The chain is folded in a uniquely defined configuration, in which it is held by certain side-chain hydrogen bonds. This configuration is the origin of the specific properties of a native protein. Increase in temperature and also certain substances break these side-chain hydrogen bonds, leaving the molecule free to assume new configurations, a process known as denaturation; the denatured protein is thus characterized by absence of a uniquely defined configuration. Dehydration consists primarily in coagulation of molecules without loss of their configuration.

A. H. Sturtevant and **Th. Dobzhansky**: Inversions in the third chromosome of wild races of *Drosophila pseudo-obscura*, and their use in the study of the history of the species. Fourteen sequences of inversions have been found; most geographical regions show several sequences, but no single sequence occurs throughout the whole range of the species. Study of the sequences should give a clue to their historical relationships.

Curt Stern and **Violet Rentschler**: The effect of temperature on the frequency of somatic crossing-over in *Drosophila melanogaster*. The number of mosaic spots is used as a measure of the *somatic* crossing-over. The frequency of crossing-over is not significantly different at 17° and 25°, but is lower at 30° C.

L. H. Kleinholz: Studies in reptilian colour changes. (1) A preliminary report. General darkening of the Florida chameleon (*Anolis carolinensis*) in the dark and on a dark illuminated background is due to a secretion from the pituitary. Certain regions are darkened by adrenalin or a similar substance.

F. Zwicky: An expansion-luminosity relation for novæ. A theoretical discussion of a simplified model of a nova.

Forthcoming Events

[*Meetings marked with an asterisk are open to the public.*]

Tuesday, October 6

British Association of Refrigeration (at the Royal Society), at 6.30.—Dr. Ezer Griffiths: Presidential Address.

Wednesday, October 7

Pharmaceutical Society, at 3.—Dr. F. L. Pyman, F.R.S.: Inaugural Sessional Address.

Friday, October 9

Association of Applied Biologists (in the Botany and Metallurgical Lecture Theatres, Imperial College of Science, South Kensington, London, S.W.7), at 11.45.—Discussion on "The Problems raised by the Woolly Aphis of the Apple—A Case for Team Research"*.

The Future in Education

SIR RICHARD LIVINGSTONE'S presidential address to Section L (Educational Science) of the British Association at the recent Blackpool meeting is one which should receive attention from all who are interested in educational purposes and scope. His views concerning some of our fundamental ideas on education must either be accepted —in which case far-reaching changes of thought and practice are necessary—or they must be proved to be mistaken. For our part, we believe he has put his fingers upon weaknesses which must be remedied both from the material point of view of value for educational expenditure, and from the philosophical point of view which would have education fit the masses for the tasks—and possible struggles—which lie ahead.

Sir Richard described the three-fold function of man: to make a livelihood, to be a citizen and to be a man; and he asked whether, despite our achievements since the education Acts of 1870 onwards, through which the main lines of our primary, secondary, technical and university organization were laid down, we can now claim to be an educated nation. Does our system make men and citizens? If the majority of an electorate are incapable of benefiting from what are called humanistic studies, "we must either abandon democracy or resign ourselves to be governed by an electorate which can never know what a state should be. Ancient tradition and political instinct may preserve such a democracy from disaster, but not only will its stability be precarious, but its political and spiritual life will be poor. The bad film and the betting news will be its relaxation; the bad press its literature, passion, prejudice, the catchword and the slogan will be its masters".

If the education of children ceased at fourteen years of age in the past, it mattered perhaps less than it does now. Education for leisure would have little purpose if the working man lacked leisure. "Fifty years ago the employment of leisure was no problem for any but the well-to-do who mostly wasted it. To-day it is becoming a commonplace in education." At fourteen years of age a child has made a beginning in many subjects: he has received a training which enables him to use opportunity for learning more: but he knows nothing of the forces affecting his country which, as a voter, he will help to determine. Economic and political theories are outside his range; his knowledge of literature is small, his knowledge of science smaller.

Ordinarily, the answer to such criticisms is that the school-leaving age should be raised. But it is here that Sir Richard Livingstone's first challenge appears. He does not argue *against* raising that age, but he says plainly that it will not, in itself, solve our problems. He makes the telling point that education must be adjusted not only to the natural capacities of the pupil, but also to the stage of development his brain has reached. "At the age of 14 or 15 the mind cannot cope with, if it can conceive, the subjects which compose a liberal education and are vital to the citizen." When, therefore, the Hadow Report spoke of giving a "liberal and humane" education through the schools it proposed, it was using "one of those phrases sounding seductive, but untrue, into which all of us are at times betrayed. The thing is impossible because a humane and liberal education includes subjects which a fifteen-year-old is not sufficiently adult to grasp". In short, maturity of mind is essential to humanistic studies for which full understanding demands experience of life.

What, then, is the solution ? Sir Richard is emphatic that it does not lie in secondary education "about which this age is over-credulous. . . . We must keep our faith in it, but temper it with scepticism", since it is only one part of a great picture from which, to see it as a whole, we must stand back a little.

If the value of raising the school-leaving age is moral and economic rather than intellectual, and if secondary education is insufficient, where must we turn ? One direction must be that of adult education. "In every point except the economic one, adult education has the advantage over secondary education. . . . It is given to students who desire it, who have the mental development to receive it, and have the experience of life to value and interpret it."

In this connexion it is inevitable that we should think of the Workers' Educational Association. Sir Richard Livingstone rightly emphasized the value of its work, but here, too, he rightly challenges complacency and indicates weaknesses. Our population is some 43,000,000. In 1935 there were 59,000 students in W.E.A. classes (at a cup-tie final there are twice that number !). The W.E.A. has therefore left untouched the vast mass of the population, although it has provided for their intelligentsia. Such studies as it has provided must continue, but for the ordinary man a different treatment is needed. Subjects must be brought into connexion with his outlook, his interests and his mind. To do this, Sir Richard sees that new methods must be sought, and he does not hesitate to say that "one of the reasons perhaps why so little progress has been made in adult education is that teachers have mostly been men with honours degrees who have brought to their work the methods and outlook of their own education".

There remain still the problems of post-primary education, and here Sir Richard's suggestions can be said to go back to the ideas adumbrated when the Education Act of 1918 was in preparation. Briefly, "the ideal plan might be for everyone to leave school at 15 and pass into a system where a part of the week was allotted to school, part to earning the living in some practical occupation, the proportions of each varying with the intellectual abilities of the pupil and the demands of the subjects he was studying". For our part we believe that such a system of part-time education would achieve far more than a system which merely raises the school-leaving age with the view of lengthening the period of full-time education. Like Sir Richard, we would not argue against raising the school-leaving age : but, whether that age be fourteen or fifteen or even more, we believe that an education such as Sir Richard has suggested will be best achieved if the pupil has some knowledge of and contact with the practical world. If education is a preparation for life, it cannot neglect the world in which we live. That world rests upon industrial and commercial foundations, and it is only when a pupil has had some contact with the realities found in practical occupations that he will appreciate the value and purpose of education. In Sir Richard's words, "theory will be illuminated by practice and practice by theory. At present the two are nearly always divorced. We lead a life of action without thought ; or we think in a vacuum without contact with the realities and problems of the world. Neither form of isolation is satisfactory". What happens at present is that, on reaching the school-leaving age, the great mass of pupils are expelled abruptly from educational influence : and, without it, the real significance of democratic rights and duties is lost and the possibilities of a wide adult education almost hopelessly diminished.

A scheme of part-time education may, of course, be impossible for all pupils, but even those who follow the usual path to the university might avoid suffering from ignorance of life if a layer of practical experience could be imposed between school and university. The 'sandwich system' followed by engineers is an example.

Wisely, in our view, Sir Richard Livingstone did not attempt full and detailed programmes : that, as he said, would be a fitting task for the Board of Education's Consultative Committee. But, whatever the details may be, we believe he has made out a case for serious change, and his case must either be answered or accepted. His challenge to our present system cannot be denied unless the terrible implication of the following passage can also be disputed : "At present life is so arranged that most of us do our thinking in youth at an age when we are not best fitted for it, and having left the university think, systematically, no more. What wonder that middle life finds so many men unaware of recent progress in their own field, unapt for new experiments and ideas, deeply embedded in their rut, while progress waits impatiently for their death and the arrival of the next generation !"

Natural Selection and Evolutionary Progress*

By Dr. J. S. Huxley

RATE-GENES AND SELECTION

THE results of selection at one period of the life-cycle may have repercussions on other periods and affect the species as a whole in unexpected ways. Perhaps the best example is that of intra-uterine selection in polytocous mammals, where rapidity of growth must be at a premium. This is likely to be transferred in whole or in part to post-natal life; intra-uterine selection may thus help to account for the progressive increase in size seen in so many mammalian lines during their evolution. At any rate, the converse seems to hold. One of the most characteristic features of man is a slowing down of general rate of development. Without it he could not in all probability have become fully human or biologically dominant. This condition could not have occurred until after man's ancestors ceased to have litters and began to bring forth a single young at a birth.

Haldane, in an interesting paper, discusses these and similar phenomena from the point of view of the time of action of the genes controlling them. A more comprehensive view, however, would include as still more important the genes' *rate* of action.

The concept of rate-genes provides a great simplification of the facts of recapitulation and anti-recapitulation. Whenever the rate of a process is correlated with time of onset and final equilibrium-level, a mutation causing an increase in rate will produce recapitulatory phenomena.

Conversely, a mutation causing a decrease in rate will have anti-recapitulatory effects. It will prolong the previous phase longer in ontogeny; it will not only slow the process down but also stop it at a lower level of completion, and it will remove certain previous adult characters and push them off the life-history. Many of the phenomena of so-called 'racial senescence' in ammonites may be due to phenomena of this type.

As de Beer has pointed out, when cænogenetic changes occur in the embryo or larva, the adult remaining unchanged, neither palæontology nor comparative anatomy would register any phylogenetic advance. But if now neoteny or fœtalization occurs, the old adult characters may be swept off the map and be replaced by characters of a quite novel type. This process he calls *clandestine evolution*. Garstang has suggested that it has operated on a large scale in the ancestry of vertebrates and of the gastropods.

A clear-cut small-scale example comes from the snail *Cepea*. Its non-banded varieties are produced not because their genes cause the total absence of pigment, but because they slow down pigment-formation and delay its visible onset relatively to general growth, to such an extent that growth is completed before any pigment can be formed.

This is a comparatively unimportant effect; but when major processes are affected such as metamorphosis, sexual maturity, or general rate of growth or development, the results may be far-reaching. Pædogenesis, neoteny and human fœtalization are examples.

The existence of rate-factors has an important bearing upon the problem presented by apparently useless characters. For alterations in the rate of a process will often automatically produce a number of secondary and apparently irrelevant effects. Numerous examples of such 'correlated characters', as Darwin called them, are now known.

RESULTS OF SELECTION, GOOD AND BAD

It is a common fallacy that natural selection must always be for the good of the species or of life in general. In actual fact we find that intra-specific selection frequently leads to results which are mainly or wholly useless to the species as a whole, including 'hypertelic' characters.

In other cases intra-specific selection may even lead to deleterious results. This is especially true with intra-sexual competition, between members of the same sex of the same species. We may, however, go further and proclaim with Haldane that intra-specific selection is on the whole a biological evil.

This conclusion is of far-reaching importance. It disposes of the notion, so assiduously rationalized by militarists and *laisser-faire* economists, that all man needs to do to achieve further progressive evolution is to adopt the most thoroughgoing competition: the more ruthless the competition, the more efficacious the selection, and accordingly the better the result. But we now realize that the results of selection are by no means necessarily 'good', from the point of view either of the species or of the progressive evolution of life. They may be neutral, they may be a dangerous balance of useful and harmful, or they may be definitely deleterious.

---

* *Continued from p.* 573.

EVOLUTIONARY PROGRESS

This question of evolutionary progress remains. It is not true that the use of the word *progress* is a mere anthropocentrism. There *has* been a trend during evolution which can rightly be called progressive and has led to a rise in the level of certain definable properties of organisms. The properties whose rise constitutes biological progress can be defined in the broadest terms as control over the environment and independence of it. More in detail, they consist in size and power, mechanical and chemical efficiency, increased capacity for self-regulation and a more stable internal environment, and more efficient avenues of knowledge and of methods for dealing with knowledge. One-sided progress is better called specialization.

As revealed in the succession of steps that led to new dominant forms, progress has taken diverse forms: at one stage, the combination of cells to form a multicellular individual, at another the evolution of a head; later the development of lungs, still later of warm blood, and finally the enhancement of intelligence by speech.

So much for the fact of progress. What of its mechanism? It will be clear that if natural selection can account for adaptation and for long-range trends of specialization, it can account for biological progress too; for progressive changes have obviously given their owners advantages. There is no more need to postulate an *élan vital* or a guiding purpose to account for evolutionary progress than to account for any other feature of evolution.

One somewhat curious fact emerges from a survey of evolutionary progress. It could apparently have pursued no other course than that which it has historically followed. For example, the final step taken in evolutionary progress to date is that to conceptual thought. We see, however, that this could only have arisen in a monotocous mammal of terrestrial habit, but arboreal for most of its mammalian ancestry. All other known groups of animals are ruled out. Conceptual thought is not merely found exclusively in man: it could not have been evolved on earth except in man. Only along one single line is progress and its future possibility being continued—the line of man.

THE EVOLUTIONARY FUTURE

What of the future? Man is not destined to break up into separate radiating lines. For the first time in evolution, a new major step in biological progress will produce but a single species. We can also set obvious limits to the extension of his range. Thus the main part of any large change in the biologically near future must be sought in the improvement of the brain.

In any case, one important point should be borne in mind. After most of the major progressive steps taken by life in the past, the progressive stock has found itself handicapped by characteristics developed in earlier phases, and has been forced to modify or abandon these to realize the full possibilities of the new phase.

Man's step to conscious thought is perhaps more radical in this respect than any other. By means of this new gift, man has discovered how to grow food instead of hunting it, and to substitute extraneous sources of power for that derived from his own muscles. For the satisfaction of a few instincts he has been able to substitute new and more complex satisfactions, in the realm of morality, pure intellect, æsthetics and creative activity.

The problem immediately poses itself whether man's muscular power and urges to hunting prowess may not often be a handicap to his new mode of control over environment, and whether some of his inherited impulses and his simpler irrational satisfactions may not stand in the way of higher values and fuller enjoyment.

Man seems generally anxious to discover some extraneous purpose to which humanity may conform. Some find such a purpose in evolution. The history of life, they say, manifests guidance on the part of some external power; and the usual deduction is that we can safely trust that same power for further guidance in the future.

I believe this reasoning to be wholly false. Any purpose we find manifested in evolution is only an apparent purpose. If we wish to work towards a purpose for the future of man, we must formulate that purpose ourselves. Purposes in life are made, not found.

The future of man, if it is to be progress and not merely a standstill or a degeneration, must be guided by a deliberate purpose. This human purpose can only be formulated in terms of the new attributes achieved by life in becoming human. Human purpose and the progress based upon it must accordingly be formulated in terms of human values; but it must also take account of human needs and limitations, whether these be of a biological order, such as our mode of reproduction, or of a human order, such as our inevitable subjection to emotional conflict.

Obviously the formulation of an agreed purpose for man as a whole will not be easy. But let us not forget that progress *can* be achieved. After the disillusionment of the early twentieth century it has become as fashionable to deny the existence of progress, as it was fashionable in the optimism of the nineteenth century to proclaim its inevitability. The truth is between the two extremes. Progress is a major fact of past evolution; but it is limited to a few selected stocks. It may continue in the future; but it is not inevitable—man must work and plan if he is to achieve further progress.

Our optimism may well be tempered by reflection on the difficulties to be overcome. None the less, the demonstration of the existence of a general trend which can legitimately be called progress, and the definition of its limitations, is a fundamental contribution to thought; and we zoologists may be proud that it has been made, chiefly from the zoological side, by evolutionary biology.

Production and Technical Application of High Voltages

THE discussion on September 14 in Section A (Mathematical and Physical Sciences) of the British Association, on the production and technical application of high voltages, was one of those selected by the Council of the Association as having a direct bearing on the life of the community. The high-voltage transmission system connecting our major power stations, and the extensive use of X-rays in hospitals, are but two examples of the impact of high-voltage science upon society, and the extent of the applicability of this science is increasing rapidly. In no other science are physics and engineering more interdependent, and it is significant that nuclear physics would have been almost a closed book without the application of high voltages.

High voltages are familiar to us in four forms: low-frequency alternating voltages, unidirectional impulsive voltages, high-frequency alternating voltages and constant voltages. The engineer is for the most part concerned with the first three forms, the normal and the abnormal types of voltage appearing on transmission lines. The lines and the station apparatus of the 132 k.v. 'Grid' in Great Britain are tested up to two or three times normal line voltage with low-frequency alternating voltages, whilst abnormal voltages—such as surges due to lightning or switching operations—up to ten times normal operating voltage may appear on the lines. Thus engineering laboratories equipped to supply 500–1,000 k.v. at power-frequencies, and 1½ million volts from impulse generators, are necessary to test all apparatus for use on high-voltage systems, and to be in the van of immediate requirements. Constant potentials have been mainly used for radiography, X-ray therapy and physical research, and there appears to be an immediate need for voltages of the order of one million for research on nuclear physics and X-ray therapy.

There are many problems confronting the supply authorities of the 'Grid' which arise at the normal transmission voltage of 132 k.v. Among these may be mentioned the effects of corona, atmospheric pollution, gaseous discharge within the voids in so-called solid insulation, and power arc discharges initiated by atmospheric conditions and other causes, as enumerated by Mr. C. W. Marshall of the Central Electricity Board. The manufacturer is equally concerned with these problems and is constantly evolving new designs and new materials for use in high-voltage apparatus better able to withstand these destructive effects. Electrical gradients used in solid dielectrics are far lower than the theoretical permissible gradients referred to by Dr. S. Whitehead, of the British Electrical and Allied Industries Research Association (E.R.A.), on account of the inherent fluctuations in quality of dielectrics, our lack of knowledge of the behaviour of dielectrics over a period of many years when subjected to thermal changes and mechanical forces, and also on account of the dangerously high over-voltages which are known to occur on lines. It has been estimated that these over-voltages are responsible for 75 per cent of all failures of supply systems.

As Mr. R. Davis, of the National Physical Laboratory, pointed out, studies of the behaviour of dielectrics under impulse voltages are still in their infancy, there being so many variables influencing breakdown, such as wave shape and polarity of the applied impulse, electrode shape, and medium of immersion, temperature, and number of applied impulses. Moreover, our knowledge of the nature of surges arriving at terminal stations is all too meagre: information is being obtained by cathode ray oscillographs and lightning current recorders on lines all over the world, but effective measures are not yet available to prevent damage due to lightning. In this connexion it is interesting to note that the E.R.A. has available a 1¼ million volt impulse generator (Fig. 1) with which to study the effects of artificially produced surges on lines and cables, this voltage being adequate to spark over the line insulation of the

'Grid'. The effects of lightning currents of 100,000 amperes have yet to be investigated, and Prof. H. Norinder, of Uppsala, Sweden, gave a brief account of the surge current generator and the effects of large currents on electrodes and earthing materials.

In the realm of atomic physics constant potentials are favoured, as they will produce the most stable source of high-speed ions for nuclear disintegration experiments. The five-million volt generator built by Dr. van de Graaf represents the most outstanding example of high-voltage generation, but is only capable of producing one milliampere at full voltage. Thermionic valve circuits can give greater powers, but so far voltages much in excess of one million have not been produced by such means. For X-ray therapy, now so widely used in the treatment of all forms of tumours, voltages up to 250 k.v. have been used, but higher voltages are essential if the effects of short wave X-rays are to be compared with those of the much feebler γ-rays from 5-gram bombs of radium. A number of such high-voltage X-ray tubes is now in operation at voltages of 500–800 k.v. One of the most original and successful tubes has been made by Mr. Sloan in Berkeley, California, who conceived the idea of generating a continuous high-frequency alternating voltage in the same vacuum chamber as the filament and target of the X-ray tube.

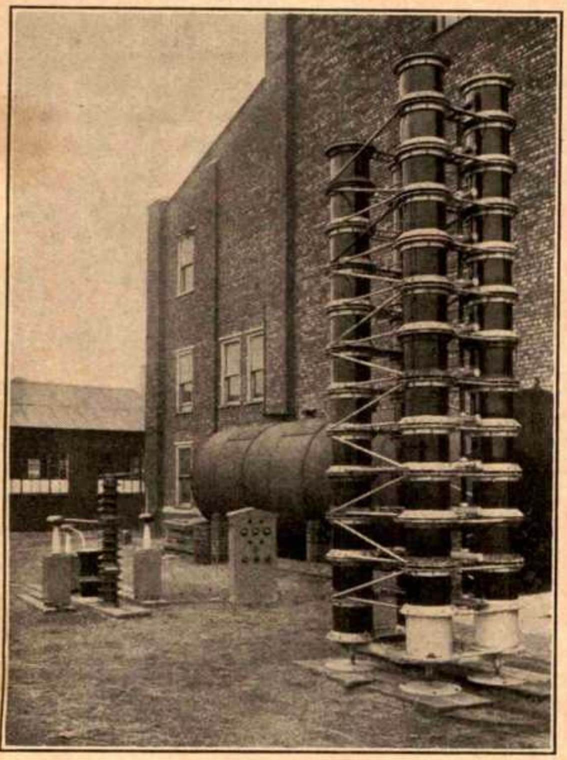

FIG. 1. 1½ million volt outdoor type impulse generator for use by the E.R.A. on the high voltage lines of the 'Grid'.

Dr. G. W. C. Kaye, of the National Physical Laboratory, described his recent researches on the measurement of γ-radiations, and announced that by using an ionization chamber large enough to absorb all the fast electrons liberated in air by the γ-rays, unification of the X-ray and γ-ray dosage measurements has been achieved. Of course, in practice it is not necessary to use a 'free air' chamber for the measurement of γ-rays or very high voltage X-rays; the 'free air' chamber may be replaced by a chamber having walls thick enough to absorb all the fast electrons.

An increasing use for constant voltage generators, widely affecting the community, is for the electrostatic precipitation of dust. Though a very old process of great simplicity, it has only recently been applied on a large scale for the detarring of gas, removal of poisonous fumes such as arsenic, and the elimination of dust from power-station flues. In one of the large municipal power-stations an electrostatic precipitator removes no less than 1,000 tons of dust per week which otherwise would be emitted from the chimney.

The measurement of high voltages presents a diversity of problems. Low-frequency alternating voltages may be measured by sphere spark-gap (a secondary standard) or by a crest voltmeter (a primary standard involving the measurement of the charging current of a standard condenser). The design of the condenser for one or more million volts presents the major difficulty as the condenser must be isolated from all sources of corona current. For lower voltages the condenser may be placed in a compressed gas chamber, or the new precision spark gap devised by Prof. W. M. Thornton may be used. This gap consists of parallel plates with rolled edges across which the field strength is uniform, so that sparking occurs with greater uniformity than occurs between spheres. For impulse voltages, however, this gap is not much superior to the sphere gap: an accuracy of one or two per cent is obtainable, provided that the spacing between spheres does not exceed the radius of the sphere and provided that the impulse wave front is at least one microsecond in duration. In shorter times than this, the gap measurement may be seriously in error, and the only reliable standard is the capacitance potentiometer and cathode ray oscillograph: the accuracy of measurement is then not greater than a few per cent. Constant potentials may be measured by the resistance voltmeter if sufficient power is available: for the electrostatic belt-type generator an electrostatic alternator voltmeter has been evolved which gives fair accuracy.

T. E. A.

The Architecture of Life

SECTION I (Physiology) of the British Association arranged a discussion at Blackpool under this title, in which Sections A (Mathematical and Physical Sciences) and B (Chemistry) took part. This discussion was concerned with some of the evidence bearing on the problem of the fundamental structure of the cells of animal organisms. In a wide and imperfectly explored field such as this, papers dealing with experimental data tend to appear rather unrelated and miscellaneous. What follows is not so much a summary of the papers as an impression of the main features of general interest.

Introducing the subject, Mr. A. D. Ritchie said that the advance of knowledge in the biological sciences depends upon an understanding of structure. In the history of science, the first stage was the development of anatomy, which revealed the relations and functions of those parts and organs of the body that are visible to the naked eye. The second stage was the development of microscopical technique which revealed the cellular structure of tissues, the functional relations of cells to one another, and, to some extent at least, the structure of the cells themselves. These methods have now accomplished most of their work. The third and the last advance will be the elucidation of the molecular architecture of the living cell. No possible improvement in microscopic technique can make structures so small as 10^{-5} cm. directly visible. The range of molecular magnitudes lies below this, say 10^{-6} cm.–10^{-8} cm. No one method of attack is going to reveal structures of this order, but only the co-operation of many different methods making use of all the resources of physics and chemistry.

Dr. D. M. Wrinch dealt with what is perhaps the central problem, that of the structure of proteins. The foundations of our knowledge have been laid by the labours of the organic chemists using the classical conception of Fischer, that proteins are built up of α-amino acids joined by the peptide linkage. Their results can now be extended by means of two new physical methods. By Svedberg's centrifuge method the size and shape of molecules of proteins in solution can be determined. By the X-ray method Astbury has obtained information about the molecular structures of keratin fibres and the protein of muscle, and Bernal about soluble crystalline proteins. The chief difficulty has been to understand the transition in structure from the globular form of the soluble crystalline state to the long chain structure of the denatured state and the fibres. The 'cyclol' scheme put forward by Dr. Wrinch gives promise of a solution. According to this conception the amino acids are linked in patterns of condensed six-atom rings. The possible patterns of this type are limited in number and their configurations can be worked out geometrically. The tautomeric change from the cyclol arrangement to the fully extended straight chain through the intermediary of folded chains becomes intelligible. There can be little doubt that all the ordinary proteins have the same kind of skeleton holding them together, so that a general solution of the structural problem is possible.

There is, however, a very different kind of protein-like material, the nucleo-proteins, the main structural constituents of the chromosomes of the cell nucleus. Geneticists have shown that the carriers of the hereditary characters are to be found here, and that they are specific and definitely localized. Fortunately, some chromosomes are so large that details of their structure are visible under the microscope. The molecular basis of the chromosome, Dr. Wrinch suggested, consists of bundles of straight chains of mainly basic amino acids bound together by combination with transverse bands of nucleic acid molecules—a suggestion that the most recent work tends to confirm.

Attached to the central structural skeleton shared by proteins in common are the side chains of the amino acids, which confer on each one its peculiar and specific properties. The importance of these specific properties comes to light in investigations of quite a different type. Dr. J. H. Quastel pointed out that for the catalysis of the chemical reactions brought about by living organisms, it is necessary to assume definite spatial arrangements of the enzyme systems concerned. Destruction of the normal cell structure stops some of the chemical reactions but not others. Experiments with bacteria have shown that while one chemical reaction can be blocked by the presence of an inactive substance on the active surface, another can proceed normally, so that the two must occur in different places and each place is specific for catalyzing one type of reaction. In the active cell there are simultaneous and successive reactions linked together in a way that implies not only definite patterns of reactive groups in the cell structure, but also some means for separating and restricting the diffusion of the soluble substances that undergo chemical change.

Dr. P. Eggleton's paper dealt with some aspects of this very difficult subject.

If a dead muscle is suspended in Ringer's solution, dissolved substances can diffuse freely into the whole of the water of the tissue. When the muscle is alive, most electrolytes can diffuse into one third only of the water it contains; the remaining two thirds are inaccessible to them. Glucose also has access to one third only, but urea can diffuse freely throughout. Histidine can diffuse throughout, but not its derivative carnosine. It is impossible at present to understand the partitioning mechanism underlying these facts, but some mechanism there must be.

The electrical potentials that are developed at cell surfaces are generally believed to be due to unequal concentrations of electrolytes on the two sides. The frog's skin develops such a potential between its two surfaces, but only so long as oxidative chemical reactions are going on, presumably to provide energy for maintaining a concentration gradient. Mr. O. Gatty has found that specific types of chemical reaction are necessary for this purpose, and is endeavouring to work out their course in detail.

Mr. J. S. Mitchell's experiments have been concerned with a rather special problem, the chemical changes in proteins brought about by ultra-violet light; but the method used is one of very general interest and great importance. It is to study the process in monomolecular films spread on a water surface. In such films the molecules can be definitely orientated and molecular structures and transformations may be studied directly. Many important cell constituents and other substances of biological interest can form monomolecular films, so that this very powerful method can be applied to them.

Obituary

Dr. J. B. Charcot

THE wreck of the polar yacht *Pourquoi Pas?* in a furious gale on the coast of Iceland on September 16, with the loss of all on board but one, was a tragic but not an inglorious end to a famous ship and to the life of the brilliant explorer whose career was so closely bound up with her for nearly thirty years.

Jean Baptiste Charcot was born in 1867, the son of a famous physician and neurologist, Prof. J. M. Charcot. He studied medicine in Paris and was for a time an assistant in the Pasteur Institute. Although he published several papers on medical subjects which were not without merit, circumstances determined that his reputation was to rest not on his professional achievements but on the outcome of his devotion to the sport of yachting.

Charcot's love of the sea brought him under the influence of the revival of polar exploration at the beginning of the present century and fired him to take a part. He raised funds for the purchase and equipment of a small ship, renamed the *Français*, for an arctic voyage, but changed the scene of his exploration to the Antarctic and sailed in 1903 with the intention of searching for the missing expedition of Otto Nordenskjöld in the Weddell Sea. When in South America he heard of Nordenskjöld's relief, and took the *Français* to the west side of Graham Land, there to continue the work begun by Gerlache in the *Belgica*. He reported the existence of Loubet Land south of Graham Land, and pushed on within sight of Alexander I Land; but the main value of the expedition lay in the physical observations and natural history collections made with the aid of his efficient scientific staff during two years.

On his return, Charcot secured Government support for a second expedition, and after a close study of the British, German and Norwegian polar ships, he had the *Pourquoi Pas?* designed to unite the best features of them all. In her he cruised for two years, 1908–10, to the west and south of Graham Land, giving precision to the somewhat nebulous lands seen from the *Français*. He explored the coast of a large island south of the Antarctic Circle to which he gave the name of Adelaide Island, believing it to be an extension of the small island so named by Biscoe in 1832. South of Adelaide Island he discovered a large inlet which he named Marguerite Bay and a new land south of Alexander I Land to which he gave the name of his father. These lands he could not approach, and he believed them to be islands lying off the Antarctic continent. As on the previous expedition, the main value of the researches on the *Pourquoi Pas?* came from the very extensive series of magnetic, meteorological and oceanographical observations and the collections of geological and zoological specimens.

After completing the publication of his results, Charcot continued to make oceanographical summer cruises in the *Pourquoi Pas?*, especially in the Greenland Sea and along the west of Scotland. He was one of the very small number of sailors to effect a landing on the remote islet of Rockall, 185 miles west of St. Kilda, and he acquired an intimate knowledge of the complex coasts of the Outer Hebrides. At the beginning of the Great War his Government insisted on placing him in the Army medical service, but he succeeded in proving that he was a better sailor than a surgeon, and received a commission in the French Navy. Later he was given command of a British vessel with a combined French and British crew, and in her he rendered valuable service by preventing the establishment of enemy submarine bases in the desolate harbours of the west of Scotland which he knew so well.

After the War, Charcot continued to visit East Greenland on summer training cruises with young French sailors. He made a trip to Scoresby Sound in 1931 to select a site for the French station for the Polar Year observations of 1932–33, and afterwards transported the party of French physicists to and from the Sound. He rendered willing and efficient help to many of the recent Greenland expeditions. To young explorers Charcot was always a generous friend and a wise counsellor, and he gave the full benefit of his experience to Mr. Rymill of the British Graham Land expedition which is now in the field.

Charcot was a man of great personal charm and high culture. His literary style was clear and graceful, and his speeches on his many visits to England were always bright and to the point, for he had a perfect command of the English language and a gift for making enduring friendships. Apart from his scientific writings and his polar narratives, he was the author of a very attractive book on Christopher Columbus in which historical critics recognized the value of the interpretation of Columbus's voyages by a scientific man with a practical knowledge of seafaring.

Charcot's genius won for him full recognition as a leading man of science both at home and abroad. He was a member of the Institut de France and of the Academies of Sciences and Marine, received the gold medals and honorary membership of all the chief geographical societies of the world, and at the time of his death was president of the Paris Geographical Society.

Hugh Robert Mill.

Dr. A. Anderson

Dr. Alexander Anderson, whose death at the age of seventy-eight years occurred on September 5, was a physicist and mathematician of note. He was professor of experimental and mathematical physics at University College, Galway, for almost fifty years. He was one of the last holders of the joint chairs of experimental and mathematical physics, a distinction shared with Prof. Morton of Belfast, who paid a graceful tribute to him in *The Times* of September 10.

Dr. Anderson was born in 1858. He studied in Queen's College, Galway (as it was then called), and graduated in 1880. He won an entrance scholarship to Sidney Sussex College, Cambridge, in 1881. He was sixth wrangler in 1884. After a short period in the Cavendish Laboratory under Sir J. J. Thomson, he was appointed professor at Galway in 1885. He became president there in 1899 and held both offices until his resignation in 1934.

Anderson is perhaps best known for his method of measuring self-inductance, which is in general use in laboratories of physics and electrical engineering. Two other of his methods have become standard practice, namely, his method of measuring surface tension and his method of measuring the viscosity of a gas. From 1890 onwards he published many papers in experimental and mathematical physics on optics, electrostatics, electromagnetics and relativity. Of his researches in experimental physics, possibly the most important is his contribution to the theory of contact differences of potential. In mathematical physics his papers mainly deal with new methods of approach to older theory.

The remarkable thing about Anderson was his really wide knowledge of experimental and mathematical physics and his continuous keenness as a teacher, especially of advanced students. I remember hearing the late Prof. McClelland, his most distinguished student, state many years ago that it was usual for his advanced lectures on mathematical physics to go on continuously for three hours, and this was his practice almost up to his retirement. He simply revelled in physical and mathematical problems. Personally Dr. Anderson was a most kindly man with a marked sense of humour. M. P.

Prof. Antoine Meillet

We regret to record the death of M. Antoine Meillet, professor of philology at the Collège de France, and president of the Historical and Philological Faculties at the École des Hautes Études, Paris, which took place at Châteaumeillant (Cher) on September 22, at the age of seventy years. Prof. Meillet was born at Moulins (Allier) on November 11, 1866. He became a lecturer in the École des Hautes Études in 1891. From 1904 until 1906 he was a professor of the École des Langues Orientales Vivantes and in the latter year was appointed to the chair of comparative philology in the École de France. M. Meillet was regarded as one of the most eminent philologists of the day, his researches extending over the whole field of the Indo-European and Iranian languages. His "Introduction à l'Étude Comparative des Langues Européennes", first published in 1897, has been through many editions, the last appearing in 1934.

We regret to announce the following deaths:

Prof. Henry Le Chatelier, For. Mem. R.S., and honorary fellow of the Chemical Society, on September 17, aged eighty-five years.

Brig.-General Sir Brodie Haldane Henderson, K.C.M.G., C.B., president in 1928–29 of the Institution of Civil Engineers, who designed the Lower Zambezi Bridge, on September 28, aged sixty-seven years.

Lieut-Colonel R. Knowles, C.I.E., acting director of the Calcutta School of Tropical Medicine, known for his work on medical protozoology, on August 3, aged fifty-two years.

Dr. A. H. Mackenzie, C.S.I., C.I.E., pro-Vice-Chancellor of the Osmania University, Hyderabad, who was a member of the recent Quinquennial Reviewing Committee of the Indian Institute of Science, Bangalore, on September 26, aged fifty-six years.

News and Views

The University of Sheffield

THE University of Sheffield, although only a little more than thirty years old, has taken an established place among the universities of Great Britain, and is attracting an increasing number of students. Recent years have witnessed some important developments and additions to the buildings, including a new department of mining, a school of dentistry, hostels for men and women and a new students' union. These additions have been largely due to specific gifts to the University. But in nearly all departments the present buildings are overcrowded. Teaching and research are carried on under conditions discouraging and hampering to both students and staff. Moreover, the limited resources of the University, imperilled by recent falls in rates of interest, limit the possibilities in securing the best men to fill vacancies on the staff and keep salaries below the usual level of other universities. To meet the urgent requirements for buildings, equipment and endowment, the University has issued an appeal for £250,000. Not less than £450,000 is required for complete fulfilment of requirements, but the lesser sum represents the minimum for outlay that is long overdue.

THE departments suffering most are medicine, geography, architecture, engineering and metallurgy. It is proposed to begin with the building of a new wing as part of a more comprehensive scheme. This wing will accommodate botany, zoology and geography, thus liberating other rooms occupied by these subjects. Engineering and metallurgy will find further accommodation by the acquisition of new land adjoining the applied science department of the University. The completion of these buildings would for a few years relieve a congestion that has become intolerable. But equally urgent is the provision of further space for the growing library. The present library, with space for only one year's normal addition of books and periodicals, and reading space for only a small number of students, must be extended. The proposal is to add to the library the present assembly hall, known as the Firth Hall, which is much too small for its present purpose and has very bad acoustic properties. This will entail the building of a new assembly hall of adequate size. For the main extensions the University already has the land, but the houses that occupy it will have to be demolished. Some of them at present accommodate in small and unsuitable rooms departments in the faculties of arts and law. Further land, however, is urgently required for the extension of playing fields for the growing number of students. Plans for the completed university have been prepared by Mr. T. Lodge and are published in the pamphlet which the University has issued. The gift of large sums to the universities of other large industrial towns has set an example which it is hoped may be followed in Sheffield now that the economic depression seems to be passing. Contributions to the extent of £54,000 have already been promised, including a sum of £10,000 from Sir Robert Hadfield, to whom the University is already indebted for generous gifts in the past.

New Laboratory for Research in Aeroplane Materials

ON October 3, Mr. D. R. Pye, deputy director of technical development at the Air Ministry, formally declared open the laboratories of Aero Research Ltd., Duxford, Cambridgeshire, by setting in motion a press of 1,300 tons capacity. The ceremony was to have been performed by Mr. H. T. Tizard, chairman of the Aeronautical Research Committee, but he was unfortunately prevented at the last moment from doing so by illness. Aero Research Ltd. is a private research organization working in co-operation with Messrs. the de Havilland Aircraft Co. Ltd. and with the Department of Scientific and Industrial Research, chiefly on synthetic resin materials. A number of demonstrations was given of the properties of the materials developed, and it was shown that the apparent brittleness in static fracture is counterbalanced by a high energy absorption which results in a remarkable freedom from 'notch sensitivity'; at the same time the amorphous structure of the material gives exceptionally good fatigue properties. Controllable pitch airscrew blades were shown, designed and manufactured by the de Havilland Aircraft Co. Ltd. from material supplied by Messrs. Bakelite Ltd., which had withstood successfully severe tests in addition to sixteen and three quarter hours actual test flying (involving continual changes of pitch) and fifty engine backfires. Other demonstrations were given of X-ray apparatus, photoelastic apparatus, special testing machines and of the utility of mass balancing in preventing wing flutter.

Records of Bird-Song

ON October 6 a private hearing was given by Messrs. H. F. and G. Witherby of some wonderfully successful gramophone records of British birds singing in their natural haunts. These are to be issued next week with a book on "Songs of Wild Birds" by Mr. E. M. Nicholson, said to be the first work to be published in Great Britain with auditory as well as visual illustrations. The records themselves were made by Mr. Ludwig Koch, with the assistance of Mr. C. Horton-Smith and the technical co-operation of the Parlophone Company. The material given on two double-sided disks, running for twelve minutes in all, has been selected from a large number of recordings. The practical difficulties to be overcome were obviously great, but the results obtained are well worth much labour. The songs of such musicians as the nightingale and blackbird are beautifully reproduced; the characteristic strains of lesser songsters like the chaffinch and willow-wren are faithfully recorded; and the calls of cuckoo and dove—even the non-vocal drumming of the spotted woodpecker —lend pleasing variety. The quality is incomparably superior to that of previous records obtained from captive birds of a few species. These records will certainly give much pleasure and useful instruction: they may also provide valuable opportunities for analytical study of bird music. No doubt more will be made, for different kinds of birds, now that the example has been set. It is clear, too, that there are other subjects to which this interesting innovation of the 'sound book' may in future be applied.

Advances in Radium Therapy Technique

TELERADIUM therapy progresses in Great Britain, and more than one big unit is now established, for, apart from those centralized under the control of the Radium Beam Therapy Research, there is a 4 gm. unit at Westminster Hospital's Radium Annexe, where physicists and engineers have combined in devising an efficient form of distant electrical control. The radium container is suspended from a rotating beam bolted to a steel girder. This container weighs about 70 lb., and the transfer of the radium in it after application to the patients, to a massive safe for purposes of custody, is carried out electrically. There is no actual handling of the radium by any of the staff, the operator being 14 ft. from the patient's couch. Another interesting feature of the container used is that it carries a collar of platinum in order to reduce scattering of emergent rays to a minimum. These technical developments in the construction of big units of radium are very welcome, because the ordinary methods of protection for the personnel which are quite efficacious in the case of X-rays are inapplicable with penetrating gamma radiation.

The New Fulham Electrical Power Station

THE new power station at Fulham on the banks of the Thames was opened formally on September 26. It occupies an area of 15 acres and has a river frontage of 1,300 feet. It is an extension of the existing plant of the Metropolitan Borough of Fulham, but the disparity between its size and the demand required for the borough shows that the new station is an undertaking to serve the Grid. Two sets of 60,000 kilowatts each were installed this year and a third set is now being added. The boiler house is at right angles to the river and the turbine room is parallel to the river. Two white reinforced concrete chimneys three hundred feet high are already built, and when the station is completed there will be four of them. Three colliers have been ordered, each of them capable of carrying 2,300 tons of coal, and the jetty has three travelling cranes each capable of handling 175 tons an hour. The cranes pass the coal to weighing machines, whence it is fed to the furnaces on two belt conveyors which run at 300 feet per minute. Using only two cranes enables a collier to be unloaded in 6½ hours. When complete and working at approximately half its maximum power, the station will consume roughly 2,000 tons of coal per day. The final fleet of colliers will consist of six boats capable of sea voyages and of passing under the seventeen bridges up the River Thames to Fulham. The new station has a dignified appearance and in conjunction with the Battersea power station on the opposite bank of the Thames will enable the Central Electricity Board to balance the London load.

THERE has been considerable opposition to the location of 'super' stations in urban areas, mainly on the ground that their chimneys emit grit and noxious vapours. But the gas washing plants at Fulham are so efficient that this objection has little weight. Each boiler is provided with sulphur extraction plant in the form of two separate units each provided with a separate induced draught fan. The sulphur extraction plant employs grid packing irrigated by a liquor containing suitable alkali so as to maintain intimate contact between the boiler gas and the washing liquor. The liquor system is known as the Howden non-effluent system. The washing medium is constantly recirculated and purged in order to keep the concentration of solid at the best value. The solids extracted are dealt with by a separate and external settlement plant. The amount of liquor recirculated through a complete washer for one boiler unit is 13,000 gallons per minute. Each complete plant is capable of handling 105,000 cubic feet of gas per minute, and the extraction efficiency for sulphur and grit is 98 per cent if the coal have a maximum sulphur content of 1·7 per cent.

The Electricity Grid

MR. H. HOBSON, in a paper read to the recent World Power Conference at Washington, pointed out some of the advantages that have accrued to Great Britain from the electricity grid. The present trend of the national output of electric supply makes it clear that, before the end of the first ten years of its operation, the system will have effected great economies without cost to the country. In the last three years alone, fuel costs per unit have been reduced 15 per cent and thermal efficiencies have risen more than 12 per cent. In 1925 the reserve generating plant was about 2 million kilowatts, against an aggregate maximum demand of less than 3 million. Last year the reserve showed no increase although the aggregate maximum demand was greater than 6 million. There is one point that is being seriously considered by the Air Raid Precautions Department of the Home Office. There is no doubt that the grid with all its associated superstations will be much more vulnerable to aircraft action in war than the old regime with its independent power stations and few overhead lines. Anti-aircraft forces would doubtless be a help, but permanent protection by camouflage or otherwise would be very difficult. Unless a super-power station were taken absolutely by surprise, palliative measures could be devised to prevent damage to the stations linked with it.

Estimates of Future U.S. Power Supplies

SOME conclusions from the reports given at the third World Power Conference as to how long petroleum, coal, natural gas and water power will last in the United States, have been issued by Science Service, Washington, D.C. There is a possibility of a shortage of domestic petroleum so early as 1940, and by 1945 the shortage may be serious. There is no cause for alarm in the figures reported, but wasteful methods of drilling and using are deplored. The question of coal conservation is considered immediate and urgent. The life of the coal resources at the recent maximum demand is about 2,000 years. With the probable increased demand of the future, the life may be measured in hundreds of years only. For natural gas the known domestic reserves are seventeen to twenty times the annual consumption. For water power, only a small percentage of the total potential hydro-electric power has yet been developed; but in making estimates, many other factors have to be considered in connexion with navigation, recreation, wild life, soil conservation, etc. One of the reports suggests the possibility of replacing all the 'manufactured gas', usually made from coal, with the by-product gas of petroleum refineries. The second most important gas resource of America is the nearly 200,000 million cubic feet of gas which has been stripped of all the condensable constituents that can be used in motor fuel. In the generation and distribution of electric power, engineers have effected notable economies in fuel consumption and the use of materials. This is a conservation step in the right direction, but many engineers think that more careful engineering is required in the mining of coal to reduce waste. Power is also used for purposes that constitute only a waste of what the engineers have so economically produced.

Enzymologia

It is with mixed feelings that we extend a welcome to yet another scientific journal. *Enzymologia* is edited by Dr. Carl Oppenheimer, assisted by an international group of distinguished collaborators, and bears the imprint of Dr. W. Junk, of The Hague, on its cover as publisher. It is to be an international monthly journal for the publication of researches relating to the enzymes. Two parts appeared, in July and August, containing twenty papers in English, French and German, and it is stated that two further parts are in the press. The subscription price for the volume of about 400 pages in six parts is 15 Dutch florins. We write "mixed feelings" because all of us, including the libraries which are the chief subscribers to the periodical literature nowadays, agree there are already too many journals both to read and to purchase. The advantages to the specialist in having his reading mainly provided for him in one journal are considerable, but against this must be set the inevitable curtailment of his general reading, tending to produce a narrow outlook. Notwithstanding these remarks, it is clear that a welcome awaits a journal devoted to progress in enzyme chemistry, the more especially since this is a field which is due for intense cultivation, leading to marked progress during the next few years. *Enzymologia* in no way conflicts with the now popular "Ergebnisse der Enzym-Forschung", which is an annual summary. The issue of the new journal from The Hague is one more example, if such indeed were needed, of the progress of biological chemistry in Holland; the first issue begins appropriately with a contribution from a distinguished Dutchman, Prof. A. J. Kluyver of Delft.

Conversazione of the Quekett Microscopical Club

By kind permission of the Royal Society, the Quekett Microscopical Club is holding its annual conversazione in the rooms of the Royal Society at Burlington House at 7 p.m. on Tuesday, October 13. Not only will there be a large number of exhibits staged by members of the Club, but also the Committee responsible for the organization of the conversazione has been fortunate in enlisting the sympathy and co-operation of other well-known scientific workers and microscopical clubs. The Royal Society is exhibiting original communications from Van Leeuwenhoek and drawings by Hooke. In addition, exhibits have been received from the Natural History Society of Cape Town, from the Microscopical Society of Victoria, Australia, from microscopists in France, the United States and various microscopical societies in Great Britain. A series of cinematographic exhibits on microscopical, pond and other life, also of the development of the bird ovum, will be given at intervals during the evening by Messrs. Kodak, Ltd. Cards of admission can be obtained on application to Mr. W. S. Warton, 35 Doneraile Street, London, S.W.6.

The Osborne Reynolds Ridge

Since the letters on the subject appeared in Nature, the Reynolds line has been seen by readers both on fresh-water and sea-water. Some of those who have seen it, however, missed the note in the News and Views columns of the July 4 issue (p. 20), giving references extending back to a paper by Prof. Osborne Reynolds. Mr. K. G. Denbigh, of Draidland, Norton Road, Norton-on-Tees, Durham, has sent an account of his observations. He saw the line at the fort of Carrawburgh, where a spring rises in a circular pool about five feet deep and eight feet in diameter. It formed a loop, roughly circular and about twelve inches across, surrounding the spot where the water rising from the bottom broke the surface. Apart from this small area where the water was perfectly clear, the pool was, no doubt, covered with a film; he refers to pollen grains and other small vegetable matter floating on it. As Reynolds explains in his paper, the line is only stationary if the rate of spreading of the film over the clean surface of the water is balanced by the outward motion of the water. Mr. Denbigh found that the loop was sensitive to wind, contracting to a point when disturbed and expanding again when the wind died down. He also noticed and sketched the distortion of reflections of reeds where they appeared to cross the line. He watched the line for nearly an hour, until a few soap shavings thrown into the water proved to be an overdose for this sensitive phenomenon.

Progress in Seismology

THE forty-first report of the British Association Committee on Seismological Investigations includes many points of interest. A brass sphere, 18 inches in diameter, has been made by Messrs. Casella for use in the determination of epicentral distances. The positions of observatories are marked by holes and the sphere has been chromium-plated. The Committee is indebted to Mrs. H. H. Turner for providing most of the accessories that will be used in ascertaining the distances and azimuths of the epicentres. Four small earthquakes were felt in the British Isles since the last report was presented, in the Channel Islands and at Leigh, Comrie and Kinlochewe. The earthquakes in the island of Montserrat continue, though they were less frequent during the first half of 1936 than in the two preceding years. A Wiechert horizontal seismograph has been installed, in addition to a number of Jaggar shock-recorders that were made at Kew Observatory for the use of the expedition sent out by the Royal Society. The preparation of the International Seismological Summary for 1931 has been completed, and the sections for the first half of the year have been printed and distributed. The number of earthquakes included is 297. References are also made to Dr. H. Jeffreys' revised table of transmission times recently published by the Bureau Central de Séismologie, to the unusually long seismic waves associated with the South Pacific earthquake of June 26, 1924, and to the Baffin's Bay earthquake of November 20, 1933.

Megalithic Monuments of South Wales

THE latest addition to the Megalithic Survey of England and Wales ("Map of South Wales showing the Distribution of Long Barrows and Megaliths". Compiled by F. W. Grimes. Southampton: Ordnance Survey. Pp. 56 and Map: Scale 4 miles to 1 inch. *5s.*, *5s. 6d.* and *6s. 6d.* net) incorporates the results of a survey of the area covered by Sheet 7 of the Quarter-inch Ordnance Map. It is now possible for the first time, as the Director-General points out in an introductory note, to assess the distribution of the megalithic monuments of an area which has been recognized as an important centre of the culture. This region, predominantly upland, and, therefore, differing essentially from others already covered by the series, falls into two parts, a narrow coastal plain of undulating country, seldom more than 400 ft. above sea-level, in which the monuments are mainly found, and an upland, which attains its greatest heights in Brecknock Beacons, and of which a large part is above the 1,000 ft. contour line. Mr. Grimes discusses a number of questions arising out of the distribution of the monuments, not the least interesting being those relating to his omissions, a matter with which he proposes to deal at greater length elsewhere. He also raises a question of wide general interest in connexion with Stonehenge. One of the most noteworthy contributions to British archæology of the post-War years was the conclusion, at which the late Mr. H. H. Thomas of the Geological Survey arrived in 1923, that the blue stones of the inner circle at Stonehenge were igneous rock derived from the Presely Mountains and the altar stone micaceous sandstone of either the Cosheston Beds around the estuary of Milford Haven, or the Senni Beds of Carmarthen and Brecknock; but up to the present no satisfactory hypothesis as to the method of transport and route has been offered. Mr. Grimes discusses the question in the light of his survey and gives his reasons for suggesting a route by both land and water in which transport from the Presely Mountains to the sea was effected by one of three possible ancient roads which he shows.

Aleutian Islands' Skull of Abnormal Size

DR. ALEŠ HRDLIČKA, it is reported by the Smithsonian Institution, Washington, D.C., in the course of excavations on the Aleutian Islands, has brought to light a skull of remarkable size. Its cubic capacity is said to be no less than 2,005 c.c. This is the second highest skull capacity recorded, the largest being that of Turgenev, the Russian novelist, whose skull has a capacity of 2,030 c.c. Skulls of known capacity ranking next are those of Daniel Webster, 2,000 c.c., Bismarck, 1,965 c.c., La Fontaine, 1,950 c.c., Beethoven, 1,750 c.c. and Kant, 1, 740 c.c. The enormous, but imperfect, South African Boskop skull, according to one estimate, has been rated at 1,950 c.c.; but a more conservative figure places it round about 1,700 c.c. Dr. Hrdlička's excavations on the Aleutian Islands, in the course of which the present find was made, are in continuation of a series of investigations of the archæology and physical anthropology of the present and former inhabitants of Alaska and the adjacent islands, upon which he has been engaged on behalf of the Smithsonian Institution for successive seasons during a number of years. His object is to elucidate the racial affinities and chronological succession of the early peoples who migrated from north-eastern Asia to populate America. On this problem, unfortunately, his latest discovery, apart from the probability that it is no more than an individual instance of abnormal development, would appear to throw no certain light, owing to the absence of the facial skeleton.

Human History and Geographical Discovery

IN his presidential address to the British Academy in July last (London: Oxford University Press. *1s.* net) Mr. J. W. Mackail said that we are at the beginning of a new era of discovery and interpretation which is revolutionizing the whole aspect of human history. Civilizations of the past in every continent are yielding up more of their secrets. Byzantine history, art and institutions have emerged from comparative neglect to an important place in humane studies. The past ages of India, China and Japan and even Central Asia are revealing their significance. The greatnesses of Central and South America are taking their place in the panorama of the past, and undiscovered Africa and impenetrable Arabia no longer exist. But important as are the acquisition and tabulation of knowledge, the primary function of humanism is the appreciation, in the largest sense of the word, of the classics of art, music, philosophy, history and creative invention over the whole range of life as throughout the whole range of literature. The danger which menaces learning is not that of conflict of sectional interests but of a general relapse into barbarism. It is not needless to reaffirm once more our emphatic and uncompromising support of all efforts to maintain the free development of the human intellect, unhampered by autocratic interference.

Avon Biological Research

THE third Annual Report, 1934–35, describing the continuation of work on the lines approved by the Avon Co-ordinating Committee, has recently been published (University College, Southampton. Avon Biological Research. Annual Report, 1934–35. Pp. 126+3 plates. Southampton: University College, 1936. 2*s*. 6*d*.). The work is conducted at University College, Southampton, where there are special laboratories set aside for the purpose, and on various parts of the river; the main purpose being salmon research and its branches, although trout research is also included. The salmon research is approved by the Development Commissioners, who since October 1934 have kept it under their official supervision, the Treasury having granted a sum towards the expenses enabling, among other things, a junior research officer to be appointed. Much help is acknowledged. Colonel Bennet-Stanford has erected a hatchery and provided facilities for the freshwater rearing of salmon in his lakes at the head waters of the Nadder, a tributary of the Avon, more than fifty miles from the sea, and many others have assisted substantially, both financially or by individual work and advice. A rotating fish screen (described in the appended papers) has been set up on Major Napier's land at Fordingbridge, where also are experimental spawning beds. East Mill still remains the headquarters of the river. The general report deals with the importance of vermin, artificial propagation and smolt migration. Appended papers include "British Mammals and Birds as Enemies of the Atlantic Salmon" (a most interesting and important summary), and "Importance of Iodine in Relation to Fish", besides accounts of hatching and stocking experiments and of scales from the Avon trout and grayling.

Useful Birds

THREE new Advisory Leaflets dealing with some British birds of prey have been issued by the Ministry of Agriculture and Fisheries. One describes the appearance and activities of the buzzard, another those of the long-eared and short-eared owls; and in the case of each of these birds the decision is that it is beneficial and worthy of careful protection. The third leaflet discusses the tawny or brown owl and the little owl; while the former is regarded on the whole as doing more good than harm, the little owl, although it also destroys pests, has become too plentiful in many districts on account of the loss it causes to poultry-keepers and others, and is therefore in no need of protection. These leaflets with their excellent illustrations by G. E. Lodge should be widely distributed in schools; they form the best sort of propaganda for bird protection.

Destruction of 'Vermin' in Bedfordshire

LUTON MUSEUM has performed a useful service in publishing a summary of "Bedfordshire Vermin Payments", extracted by J. Steele Elliot from the records of parish officials during the sixteenth to nineteenth centuries. A recent note in these columns referred to the exceedingly limited distribution of the pine-marten and polecat in Britain at the present day; but up to 1808 the pine-marten was being killed, at 2*d*. a head, in Bedfordshire, and in forty-two parishes payment was claimed on a total of more than 6,000 polecats, the most recent record in these accounts being in 1835. It is a sorry tale of extermination.

Indian Wild Life: a New Magazine

IN an effort to encourage wider sympathy with wild life in India, a group of enthusiasts has published *Indian Wild Life*, the official organ of the All India Conference for the Preservation of Wild Life. The objects of the Conference are ambitious: to give effect in all parts of India to the provisions of the All India Convention of 1935, to encourage the preservation of fauna and flora, popularize natural history in schools, establish a natural history library, and an exchange system of literature, to establish a National Park and to publish books and pamphlets on Indian natural history, and to disseminate literature in different languages. It is a big programme, but it is worth aiming at, and well worth encouraging. To the mind of a Western reader, too great a part of the new magazine is given up to personal paragraphs, but it is encouraging to find that already one of its objects has been fulfilled, and that a United Provinces National Park is an accomplished fact—the only Park of its kind in India.

British School of Archæology at Rome

IT is announced that Mr. C. A. Ralegh Radford has been appointed director of the British School of Archæology at Rome in succession to Mr. Colin Hardie, recently appointed fellow and classical tutor of Magdalen College, Oxford. Mr. Radford is a former student of the British Schools of Archæology at both Athens and Rome; and by his excavations on prehistoric Roman and medieval sites in Britain and abroad has taken a prominent part in recent advances in archæological studies. He was appointed Inspector of Ancient Monuments for Wales and Monmouthshire in 1929, and is also a member of the Royal Commission on Ancient Monuments of that area. As general secretary with Prof. V. Gordon Childe of the First International Congress of Pre- and Protohistoric Sciences he was jointly responsible with him for much of the success of the session held in London in 1932. Mr. Radford's training and experience have been such as should enable him to preserve the necessary balance between the studies of the School in prehistoric, protohistoric and classical archæology, to which the special circumstances of Rome are perhaps less conducive than those of Athens.

Television Demonstrations in London

EXPERIMENTAL television programmes are being transmitted by the B.B.C. until further notice between 11 a.m. and 12 noon and 3.0–4.0 p.m. daily. A demonstration television receiver has been installed at the Science Museum, South Kensington, upon which the B.B.C. transmissions from the Alexandra Palace are received. The receiver has been lent by Messrs. A. C. Cossor, Ltd., and is of the type which is now available to the public for home reception. A special aerial has been erected on the roof of the Museum, and the receiver has been installed in one of the basement galleries where provision has been made for visitors to see the demonstrations. The Southern Railway has also provided television receivers at Waterloo Station for the use of ticket-holders.

Announcements

THE Thomas Hawksley Lecture of the Institution of Mechanical Engineers will be delivered on November 6 by Prof. A. Fowler, who will take as his subject "The Spectroscope and the Atom".

THE council of the Illuminating Engineering Society has awarded the Gaster Memorial Premium to Mr. Ralph G. Hopkinson, for his paper on "The Photographic Representation of Street Lighting Installations", read before the joint meeting of the Illuminating Engineering Society and the Royal Photographic Society last December; and the Silver Jubilee Commemoration Award to Mr. W. R. Stevens, for his experimental work on "Thermal Endurance of Illuminating Glassware".

THE Masters Memorial Lectures of the Royal Horticultural Society will be given in the lecture room of the Society's New Hall in Greycoat Street, Westminster, on October 27 and November 10, at 3.30 p.m., by Dr. Redcliffe N. Salaman, on "The Potato in its Early Home and its Introduction into Europe".

DR. PASTEUR VALLERY-RADOT, a distinguished Paris physician and grandson of Pasteur, who is well known for his work on anaphylaxis and asthma, has been elected a member of the Paris Academy of Medicine.

DR. ETIENNE BURNET, formerly assistant director of the Pasteur Institute of Tunis and expert in the public health organization of the League of Nations, has been nominated director of the Pasteur Institute at Tunis in succession to the late Dr. Charles Nicolle.

THE Riberi prize, founded by an Italian surgeon, for the best contribution to the progress of medicine within the last five years, has recently been awarded to Dr. Francesco Pentinalli, professor of general pathology at Florence, for his work on experimental tumours and cancer. The articles submitted for the prize numbered 273 and emanated from 38 contributors from nine different countries.

THE Indian Science Congress, which will be held at Hyderabad on January 2–8, 1937, will consist of sections of mathematics and physics, chemistry, geology and geography, botany, zoology, anthropology, agriculture, medical and veterinary science and physiology and psychology. Further information can be obtained from Dr. H. Hyder Ali Khan, Medical College, Osmania University, Hyderabad.

THE Central Office of the World Power Conference, 36 Kingsway, London, W.C.2, announces that it will publish on October 28 the first number of the "Statistical Year Book of the World Power Conference" (price £1). This volume will contain an inventory of the power resources of the world, and annual statistics, relating to 1933 and 1934, of the production, stocks, imports, exports, and consumption of solid and liquid fuels, natural gas, water power, and electricity.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:

A technical officer for experimental work with ground and aircraft radio direction-finders at the Royal Aircraft Establishment, South Farnborough, Hants—Chief Superintendent, quoting No. A. 243 (October 12).

A lecturer in mining subjects in the Municipal College, Burnley—Director of Education, Educational Office, Burnley (October 12).

A lecturer in the Department of Architecture, Building and Structural Engineering, Rutherford Technical College—Director of Education, City Education Office, Northumberland Road, Newcastle-upon-Tyne, 2 (October 14).

Chemists (male) and a junior assistant chemist (male) at H.M. Factory, Irvine—Under-Secretary of State (C. 5), War Office, London, S.W.1 (October 17).

An assistant lecturer in the Aeronautics Department, Imperial College of Science and Technology, S.W.7—Secretary of the College (October 17).

An assistant biochemical engineer in Saorstát Alcohol Factories, Irish Free State—Managing Director of the Factories, Department of Industry and Commerce, 14/15 St. Andrews Street, Dublin (October 17).

An assistant lecturer in engineering at the School of Mines, Treforest—Director of Education, County Hall, Cardiff (October 19).

A civilian technical officer in the Department of Scientific Research and Experiment, Admiralty—Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1, quoting C.E. 6024/36 (October 24).

A library assistant at the Research Department, Institution of Automobile Engineers, Great West Road, Brentford, Middlesex.

Engineers for the Public Works Department (temporary staff) of the Government of Nigeria—Crown Agents for the Colonies, 4 Millbank, London, S.W.1, quoting M/4500.

A lecture assistant and laboratory steward for the Chemistry Department, Sir John Cass Technical Institute, Jewry Street, London, E.C.3—The Principal.

A lecturer in theory of structures and structural design, and a lecturer in electrical engineering at the Medway Technical College, Gardiner Street, Gillingham—Mr. C. Colles.

Letters to the Editor

The Editor does not hold himself responsible for opinions expressed by his correspondents. He cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 646.

CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Diffraction of Light by Ultra-Sonic Waves

F. H. SANDERS[1], in a recent note in these columns, has reported excellent agreement between our theory and his experimental results. His note, however, calls for a statement from us clarifying the theoretical position. As is well known, Debye and Sears in America and Lucas and Biquard in France discovered, in 1932, that a beam of light after passing through a supersonic field breaks up into a fan of diffraction spectra. Following this discovery, Prof. R. Bär, of Zurich, carried out extensive investigations regarding the nature of the phenomenon; he obtained numerous beautiful results concerning the manner in which the relative intensities of the various diffraction spectra depend on the wave-length of light, the supersonic intensity and the thickness of the cell. He also discovered that the frequencies of light in the diffracted spectra are modulated by the sound field in a very peculiar manner depending on the order of the spectrum.

As has been remarked by many investigators, these results of Bar, and even the appearance of a large number of diffraction spectra, found no explanation in terms of the theory of Brillouin. Indeed, the existence of higher orders had been erroneously ascribed to the existence of overtones in the supersonic field. In the theory of Lucas and Biquard, which was mentioned by Sanders in his note, the laws of geometrical optics were applied to the problem, and it was assumed that the individual rays of the incident light follow paths independent of one another. This theory ignores the interference effects which are fundamental to the problem, and does not succeed in explaining the characteristic features observed in experiment.

The theory of the phenomenon initiated by us is set out in a series of papers[2]. At the outset, our purpose was to develop a theory of the simplest possible character which would satisfactorily account for Bär's experimental results. A simplification was effected by assuming that the wave-length of the sound is not too small and the thickness of the cell is not too large; in which circumstances, it can be shown theoretically from Fermat's principle that only the phase changes occurring in the passage of light through the cell need be considered. Indeed, Bar[3] reported later that the results in our papers I, II and III agreed qualitatively with most of the observed features of the phenomenon even in the general case, and in a perfectly quantitative manner when the experimental restrictions postulated by us were actually satisfied. In our papers IV and V, the restrictions mentioned above were dispensed with and the theory of the phenomenon was developed quite rigorously on the basis of the electromagnetic wave-equations. This general theory has been fully worked out by one of us (N. S. N.) and leads to a satisfactory explanation of some remarkable experimental results obtained by Dr. S. Parthasarathy[4] at this Institute. It is found that, when the light is incident obliquely to the sound waves and the latter are of sufficiently high frequency, the intensity of the diffraction spectra shows very marked asymmetry and that particular orders attain maximum intensity at characteristic angles of incidence given by a formula of the Bragg type. This is in agreement with the deductions from the theory.

Another aspect of the problem has been worked out by one of us (N. S. N.) in a paper now under publication. It has been explained why the supersonic waves can be seen directly through a microscope focused on a plane to the rear of the sound-wave cell. The theory predicts the interesting result that the grating-like pattern observed through the microscope repeats itself periodically as the focal plane of the microscope is moved away from the cell by integral multiples of a definite distance. This prediction has been confirmed quantitatively in a very recent (as yet unpublished) investigation made at this Institute by Dr. Parthasarathy. Other peculiar features of the sound field as optically observed—for example, a doubling of the number of fringes in certain positions of the microscope, and a disappearance of the fringes at certain other positions—are also indicated by the theory and are beautifully confirmed by the experiments.

Surface Markings on a Diamond

ACCORDING to the mosaic hypothesis, it is postulated that the uniform lattice structure of an ideal crystal is interrupted over narrow regions distributed periodically throughout the crystal at distances large compared with the size of the unit cell. Various forms of the hypothesis have been devised to explain anomalies in the intensity of reflection of X-rays, breaking strength and other 'structure-sensitive' properties of crystals, but the subject is at present highly controversial. Whilst many facts undoubtedly fit the hypothesis, several workers claim that some half dozen other types of fact do not fit[1]. All forms of the hypothesis including the 'lineage structure' proposed by Buerger[2] would predict non-uniformity

William Stukeley on Newton

Memoirs of Sir Isaac Newton's Life by William Stukeley, M.D., F.R.S., 1752: being some Account of his Family and chiefly of the Junior Part of his Life. Edited by A. Hastings White. Pp. xvi+86+3 plates. (London: Taylor and Francis, 1936.) 5*s.* net.

WE have reached a position when biography is taken seriously. Imagination is wanted; but in the case of great men, it is not enough to be imaginative; one requires to scrutinize the sources themselves in readable form.

William Stukeley owes his fame to Newton. He was an antiquary. According to the "Dictionary of National Biography" he is chiefly known to the public by one of his errors in reading a coin, which is the wrong thing for an antiquary to be known by. He was a friend of Newton; a Lincolnshire man like Newton. He was also at Cambridge. Though considerably Newton's junior, he afterwards saw much of Newton in London, and acquired an almost oppressive admiration for him. He afterwards went to Grantham, where he was in a favourable position to learn the truth of various stories. Hence when Conduitt, who married Newton's niece, wrote to several friends for their recollections, Stukeley was among the number, and responded.

We owe the present publication to Mr. A. Hastings White, consulting librarian of the Royal Society, to whom, as the superintendent of the British Museum Reading Room says in the foreword, "the thanks of students in so many branches of learning are due for his scholarship and never-failing readiness to help".

Mr. L. T. More regards Stukeley as "the principal source of our knowledge of Newton's personal life"; he also speaks later of Stukeley as "trustworthy"—one would add, if you take a grain of salt with his stories. He seems to have been a pre-scientific antiquary. Of Woolsthorpe, he writes, "This Mannor of Wulsthorp probably belong'd to Ulfus and took its name from him", and embarks on a page and a half about Ulf, decorated by an "in all probability" and an "I suppose". From the frontispiece to this volume, Stukeley looks a pleasant, good-humoured man. He had great opportunities, but I do not think he made the best use of them. He does not seem to have taken himself too seriously. He gives a sketch of Woolsthorpe as it was in his day, and says the house was rebuilt "not so large a form as the old house", from which we infer that the cut given in Brewster does not represent the house in which Newton was born. One would suppose that Brewster's well-known talent for inaccuracy lay in wait for him on an unnecessary occasion. But other people's boots are on the wrong feet too. Stukeley himself was not meticulously accurate. Mr. White gives an allegorical portrait of Newton by Stukeley, supported by a nude and dubious Urania (if it *is* Urania), with as many breasts as Stukeley can find room for, irrespective of the possibilities of anatomy, though Stukeley was, among other things, a medical graduate and a practising doctor.

One requires to be pretty clear as to *which* of Stukeley's writings the present volume is. Stukeley went to Grantham in 1726, the year before Newton died, and began collecting traditions. When Newton died, Conduitt wrote and asked him to contribute his collections, and Stukeley mostly sent these to Dr. Mead, who had attended Newton in his last illness. These apparently figure among the "Catalogue of Portsmouth Papers" (p. 44, No. 109), and they were auctioned with the rest by Messrs. Sotheby when the Portsmouth Papers were sold on July 13–14 of this year. Brewster consulted them, and also L. T. More. But Stukeley also made, apparently, two drafts of his letter to Mead in 1727, and kept these by him until 1752, perhaps completing them and perhaps allowing ample time for second thoughts. He drew these up twice over, under three heads. The heads should make for clearness; but they do not. They are rather conflicting, and one does not discover in the contents much trace of them. He put in the dedication, but he never seems to have taken any steps as to publishing them. One learns from the foreword to the volume under notice that Stukeley's own papers were auctioned in 1931, that is, before the Portsmouth Papers were dispersed. Afterwards, the chief MS. found its way to the Royal Society, where Mr. White copied it out and published it in the volume before us. Hence there are at least two documents by Stukeley, and one must compare, as well as one can, the present volume with what has passed through the sieve of Brewster and L. T. More, to find out whether they agree, Stukeley's papers in the Portsmouth collection not being now available elsewhere.

The result of this comparison is that the two are remarkably alike, though not quite verbatim. On the whole, we learn very little new from them, and what they do say, we would like to see confirmed from other sources. One would gather from the account of Newton's rich relations that he was always in opulent circumstances, which does not tally with his going to Trinity College in the capacity of a sizar. Among the major things we learn are that Newton was of a cheerful disposition; that he was very much attached to Grantham; that he was talkative among his own countrymen; that he was very much interested in plants and was in the habit of going "simpling"; that he used to be a good draughtsman when young; that when he had a cold, he stayed in bed until it was over;—all things that might be told of anybody. "Give me of Nelson only a touch, And I keep it, be it little or much." It is none the less a book to be read, as giving a picture of Newton and his personal habits, as he seemed to one who had seen him in the flesh. We are indebted to Mr. White for its publication.

One thing we get is a clue to the origin of the verses which Newton's former love, Mrs. Vincent, used to repeat when eighty-two years of age, which Brewster and also L. T. More attribute to young Newton, namely, they were copied out of *Eikon Basilike*, along with the drawing of King Charles I which is their subject. R. A. S.

The Naturalist Outlook in Psychology

The Natural History of Mind
By A. D. Ritchie. (Tarner Lectures delivered in Trinity College, Cambridge, 1935.) Pp. viii+286. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1936.) 15*s*. net.

THE title of this book is significant, indicating, as it does, that the author proposes a return from all the sterile systems of psychology that derive from the Cartesian separation of mind and body to the naturalistic outlook of Aristotle. He is in good company, and one of an increasing band of students of the biological sciences who, whether philosophically minded or not, are already upon the same road.

Mr. Ritchie, however, is philosophically minded, and makes use of his science to lead up to problems, vital for all philosophy, that emerge most clearly, though not exclusively, in psychology. Indeed, these are the very problems from which psychology originally arose, when men first began to speculate about the value of any kind of knowledge and the binding force of any kind of law. So far, however, as psychology is concerned, they remain problems to the end; for though this science still investigates the origin and growth of knowledge, and the belief that some actions are right and some wrong, it is left to philosophy to discuss the ultimate validity of the one and the ethical status of the others.

Because of this common sharing of subject-matter, Mr. Ritchie maintains that psychology must always remain "intimately connected with philosophy, as in the past". This is open to criticism; for, if a distinction is drawn between subject-matter and formal subject-matter, and between proximate and ultimate problems and principles of solution, the science of psychology could be differentiated from philosophy in exactly the same way as the other sciences are differentiated from it. Philosophy is not exclusively occupied with epistemology and ethics; and psychology, though it may provide the data, does not professedly deal with those topics.

Such criticism aside—and Mr. Ritchie anticipates it by remarking that his opinion is advanced "at the risk of misunderstanding and unpopularity"—"The Natural History of Mind" is intentionally a suggestive rather than a constructively conclusive book. Nearly half of it is taken up by preliminary chapters dealing, among other matters, with causation, the distinction between the living and the lifeless, the nervous system, and the functions of the brain. These preliminaries are necessary, for in the event much will turn upon the way they are treated. For example, the question of freedom (which, for Mr. Ritchie, rather than consciousness, is "the most central and illuminating fact of mental life") can only be profitably discussed in the light of an adequate theory of causality. Again, teleology (which "is not an explanation in the ordinary sense but a statement of fact, or a description") is one of those facts of which account must be taken when dealing with specific biological problems that are only generically covered by solutions of the more comprehensive problems of physics. Man, as a physical object in a physical world, is subject to physical laws ; as a living organism, he is subject to biological laws as well ; and, as a being capable of perceiving, thinking, feeling and willing humanly, it is surely arguable that even more specific laws apply also in his case. As Mr. Ritchie points out, you can prove once for all that all triangles have certain common properties ; but this does not absolve you from considering the peculiar properties of the different kinds of triangles.

Very interesting chapters are those on the brain and nervous system. They show how modern work has overthrown the reflex theory of Descartes that for so long handicapped physiology and psychology alike, and also indicate incidentally the influence of the *Gestalt* way of thinking. Their results for psychology are, however, in the main negative. The answer to the question "What does psychology study ?" which stands as title to Chapter vi, is disappointing. The science has no source of information of its own not shared by other sciences ; and it differs from these chiefly if not only by reason of the explanatory concepts of which it makes use. Mr. Ritchie writes paradoxically : "Self consciousness is a fact but not a fact that leads to knowledge about the self or the consciousness". Yet, if psychology is "the study of the embodied mind", surely this peculiar fact must lead to knowledge of some sort, that the self at least knows itself capable of feeling, thinking, willing and the like, because it has experienced itself doing so. This is no knowledge of abstract 'activities', but of an active concrete entity, from which the anthropomorphic conceptions used in physiology and the biological sciences are derived. It is noteworthy that Mr. Ritchie admits in parenthesis : "We need not enquire at present whether the categories of cause and substance even are safe from this accusation" (of anthropomorphism).

The final chapters deal with sensation, perception and cognition, and with emotion and thought, the latter containing a sympathetic criticism of Spearman's Two-Factor Theory and Principles of Cognition mainly from the point of view of linguistic defects in verbal *g* tests.

It has been said that this book is suggestive. It gives evidence of very wide reading in very many subjects ; and, while necessarily dealing with profound problems, is written with an admirable lightness of touch.

Clinical Research

Vascular Disorders of the Limbs :
described for Practitioners and Students. By Sir Thomas Lewis. (Department of Clinical Research : University College Hospital, London.) Pp. xi + 111. (London : Macmillan and Co., Ltd., 1936.) 6*s*. 6*d*. net.

THE active department of clinical research, under the direction of Sir Thomas Lewis at University College Hospital, London, has been engaged for the last eight or nine years in the study of disturbances of the circulation in the limbs. Because of their much greater surface relative to that of the head and trunk, the limbs suffer more from alterations in blood supply, and the circulation in the limbs is of greater importance. This book is not, however, an account of the scientific discoveries which have been made, but is written as a guide to the practitioner to direct his treatment of different conditions.

Many interesting observations are made. It has been customary to treat deficient circulation in one limb by keeping it warm ; Sir Thomas Lewis points out that a greater increase in circulation is obtained in the limb by warming the rest of the body. Heat applied to the body as a whole has the effect of lessening the vasoconstrictor tone in all arteries ; the arteries, therefore, dilate and admit more blood to the extremities.

A valuable analysis of the conditions grouped under the heading of Raynaud's disease is given ; Sir Thomas Lewis states that the term has been applied to a number of distinct conditions ; he applies the term Raynaud's *phenomenon* "to any state in which loss of circulation to digits occurs spasmodically, displaying itself in transient attacks of discoloration"; he uses Raynaud's *disease* to comprise cases of intermittent spasm of digital arteries. The cause of the disease is that the arteries are incapable of full expansion, being narrowed by thickening of the intima. In treatment, vasodilator substances have little or no value, though if the basal metabolism is low, the administration of thyroid is often beneficial. The section and degeneration of the sympathetic nerve supply improves the circulation to the limbs in these cases.

During the period in which the research on which this book is based has been done, Sir Thomas Lewis has been an influential advocate of the importance of clinical as opposed to laboratory investigation in the fight against disease; his book is, therefore, to be regarded as an example of what clinical research can do for the patient. That the results embody a large amount of industrious and expert observation is obvious, but they are rarely surprising, and it may be asked whether the most valuable and inspired research does not always give surprising results.

Clinical research is of course of the highest importance, for only by contact with it does the clinician learn the importance of physiology; the neglect of clinical research is responsible for the inefficient therapeutics seen everywhere to-day. But clinical methods are too limited to allow fundamental discoveries to be made; these demand the freedom which is only possible in the laboratory. If the laboratories have not been sufficiently fruitful in the past, it is the fault of the men in them, and their lack of training, rather than of the possibilities of laboratory methods.

The Biological Action of Radiation

Biological Effects of Radiation:
Mechanism and Measurement of Radiation, Applications in Biology, Photochemical Reactions, Effects of Radiant Energy on Organisms and Organic Products. (Prepared under the auspices of the Committee on Radiation, Division of Biology and Agriculture, National Research Council, Washington.) Edited by Prof. Benjamin M. Duggar, with the co-operation of Janet Howell Clark, Kenneth S. Cole, Farrington Daniels, Gioacchino Failla, Charles Packard, Henry W. Popp. Vol. 1. Pp. x+676. Vol. 2. Pp. vii+677–1343. (New York and London: McGraw-Hill Book Co., Inc., 1936.) 70*s*.

TO write a comprehensive work upon the "Biological Effects of Radiation" has now become an impossible task for any single person, and we are, therefore, especially grateful to Prof. Duggar and his collaborators for the preparation of the two volumes before us. These volumes contain forty-three essays on various aspects of the question, and give about four thousand references to original papers; while their scope ranges from pure physics and chemistry to the chromosomal aberrations which may be produced by irradiation. Two subjects are, however, specifically excluded, namely, practical considerations relating to plant production, and those special applications of rays which are concerned with radiotherapy. It is as obviously impossible for one person to write an adequate review of such a work as this, as it is for him to compile it; and all that can be attempted is to give a general idea of the vast field that has been covered.

The great difficulty encountered by all serious workers upon experimental radiology is the highly varied branches of science with which it is necessary for them to have some acquaintance. As a consequence of this, we think that the writers of these volumes have done well in their introductory chapters to lay stress upon recent developments in physics, physical measurements, and some of the general chemical effects of radiations. To the pure physicist, the introductory chapters on photons, electrons and measurements might seem elementary or even superfluous; to the biological worker we are certain that they will prove invaluable. A further complication is introduced by the fact that rays of various kinds have now become not only an object, but also a means of research.

Mutations in plants and animals have been effected by exposure to X-rays and to the rays from radium; these subjects are dealt with in a series of papers which are at once clear, succinct and comprehensive; and although any special reference to the therapeutic use of radiation is excluded, the practical bearing of this experimental work must be obvious. The science of genetics is indeed largely indebted to the use of radiations for the attainment of some of its most interesting results.

To make definite selections from the large amount of information which has been presented to us is difficult, but there are a few topics, apart from those that have already been collectively mentioned, which it may be interesting to name, so that workers in special fields may have a guide as to where an epitome of the latest information is available.

The first of these is an excellent paper on the statistical treatment of biological problems in irradiation. The need for adequate statistical presentation of the experimental data obtained from large numbers of animal experiments is obvious, and more especially is this the case when a large number of experiments have been made on, for example, the question of heredity and susceptibility to implanted tumours. Too often conclusions on these and similar subjects have been based, not only on inadequate data, but even have been reached by methods which no statistician would regard as admissible. The essay on this subject should therefore fulfil a requirement which has long been unsatisfied. Of other aspects which may fittingly be made the subject of special mention are the biological effects of 'short' electric waves, which are of particular interest at the present time owing to the extensive use that is being made of them in medicine, and the much discussed problems of mitogenetic radiation. The radiations considered range from the 'short' electric waves to the γ-rays of radioactive substances; while the biological field extends from bacteria to phanerogams and from protozoa to mammalia.

The two volumes must undoubtedly find a place in every laboratory and institution where the biological effects of radiation are the subject of instruction or investigation.

India and Mineral Development

India's Mineral Wealth:
a Guide to the Occurrences and Economics of the Useful Minerals of the Indian Empire. By Dr. J. Coggin Brown. Pp. x+335+14 plates. (London: Oxford University Press, 1936.) 15*s*. net.

THE predominant impression produced by a perusal of this handy little book is one of astonishment at the amount of information packed within so small a compass. Dr. Coggin Brown possesses the happy facility of condensing facts and preserving at the same time, even in a work of this kind, an easy style and a connected narrative. The bird's-eye view of the situation, occupying no more than a single page of the introduction, is a snapshot as complete as it is harmonious of the position of mineral development in the Indian Empire, in which is included Burma.

The introduction serves as a signpost to anyone desirous of following the progress of the country from the point of view of minerals. It reminds readers where they can consult reviews of mineral production, including brief accounts of the geology pertaining to each mineral and full bibliographical lists. The mineral and geological literature concerning India is probably the best indexed in the world, thanks to the publications of her Geological Survey and more especially to the unselfish labours of Mr. T. D. LaTouche. The construction of a work of reference is a monotonous and glory-lacking occupation, too apt to be received, like food and drink, as a matter of course, and sharply criticized for any omission or defect rather than lauded for its incontrovertible value. Those who have occasion to use such works as the indexes of LaTouche and the compendium now under review will feel inclined to follow the example of the Cambridge divine who made a point of thanking God for the men who make dictionaries, catalogues and indexes.

Within a space of 300 pages of text, the useful minerals of India are considered individually by Dr. Brown as regards occurrence, history of development, uses (in the case of some of the less common minerals), outputs and their values from early times to the present day, and comparison with imported rivals, with brief notes on their origin.

India and Burma are associated in the average lay mind with gold and precious stones, but it is with the fuels that the author very rightly commences. Apart from the pivotal importance of fuel for most industrial purposes, India's output of coal and oil greatly exceeds that of any other mineral. As the figures published in this book show, during the quinquennium ending in 1933, the value of the output of the Indian goldfields, which supply the world with about 1·34 per cent of its needs in gold, was about three tenths of the value of her coal, and less than two fifths that of her petroleum; as for precious stones, the coal production was worth nearly 450 times as much as the diamonds, rubies, sapphires and spinels together! The book is full of little suggestive side-issues and remarks on subjects such as the simultaneous import and export of paraffin wax; the recovery of gasolene from petroleum gas, and the potential uses of what remains in the manufacture of dyestuffs, solvents and anæsthetics, in the preparation of helium for aeronautics, and as a fuel for domestic and power purposes; the amount of silver leaving the country in the copper matte and the zinc concentrates; the failure of corundum mining in contrast to its success in South Africa;

the import of coal for consumption on the Giridih coalfield and the analogous importation of Persian oil for fuel purposes in the Yenangyaung oilfield of Burma.

To check every statement and figure would be to rewrite the book, but those who know Dr. Coggin Brown's reputation for accuracy will have complete confidence in accepting his statistics. As Superintendent of the Burma Party of the Geological Survey of India for many years, as Mineral Advisor to the Indian Trade Commissioner, as an officer closely associated with the Imperial Mineral Resources Bureau, and as a man with an undoubted *flair* for collecting and presenting statistical information, Dr. Brown is peculiarly qualified for the task he has so ably completed. The work closes with a bibliography which with business-like brevity includes only the latest and most comprehensive publications dealing with each mineral.

It would take an ultra-cynical mind to discover any positive defect in Dr. Coggin Brown's excellent little book, and one closes it with one regret only, and that is that its pages are so few. To increase them to any large extent would, admittedly, defeat the main purpose of the volume, but one suggestion is perhaps worthy of consideration with respect to a second edition. It is the addition of a few pages describing and commenting on the special problems which confront the adequate development of India's minerals. As examples, the following will serve: the vital necessity of persuading the Indian peasant not to cook his food with cow-dung, the selling price of which as a fuel is half its value as a manure, but to substitute coke or coal, and to increase in this way and for this worthy purpose the ridiculously low coal-consumption figure of two million tons annually by a population of more than 352 millions; the reduction thereby of the considerable imports of artificial manure; the conservation of indigenous coking coal for metallurgical requirements; the possibility of eliminating the high sulphur content from the Assam coal, which would then furnish a rich source of hard, metallurgical coke; the substitution of some other reducing agent in the place of metallurgical coke; the question of winning oil by mining in place of boring; the prospects of oil shale and artificial substitutes as rivals to the free mineral; the adequate utilization of the large gas supplies available in the country; the question of India's smelting her own zinc concentrates, copper matte, tin ore, chromite, nickel and cobalt, speiss, etc., instead of exporting them in the raw state; the problem of utilizing more of her pig iron in the manufacture of her own steel; the discovery of additional uses for the almost inexhaustible supplies of magnesite, and for the large quantities of monazite; the establishment of a sulphuric acid industry; the employment of water-power for the manufacture of aluminium from the large reserves of bauxite; the encouragement of glass manufacture to replace the enormous imports from Japan; the remedy for the rock-bursts which at depths of 1½ miles are becoming a serious impediment to further development of the gold mines.

Many of these and other problems are alluded to directly or indirectly in the text but, having in mind the number of Indian statesmen, legislators, administrators and industrialists who will find a use for the book, a definite tabulation and presentation of the problems might stimulate and direct research, and even legislature. The book purports to be a collection of facts, but the problems are also facts though their several solutions have unfortunately not yet attained that status. The suggestion is no criticism of what is in the book; what is already there is so excellent that it is excusable to want more, even if only another ten or a dozen pages.

The book will be invaluable to industrialists, Government officials, economists, statisticians, members of legislative assemblies, and all interested in a great country which, with a mineral output valued in 1928 at £24 million, is slowly taking her place in the mineral world but still has much further to go.

EDWIN H. PASCOE.

Malayan Zoogeography

Die Geschichte des Sundabogens:
eine tiergeographische Untersuchung. Von Bernhard Rensch. Pp. viii+318. (Berlin: Gebrüder Borntraeger, 1936.) 18 gold marks.

IN the present volume Dr. Rensch presents a masterly summary of the zoogeography of the Malayan Archipelago. A general account of the expedition he and his colleagues made to the Sunda region (islands east of Java) was published in 1930, and the author has now collected together not only the results of his own expedition but also of some three hundred titles dealing with the region as a whole.

The bulk of the book consists of a detailed analysis of the fauna of each island in turn. Generally speaking, only the mammals, birds, reptiles, amphibia, butterflies and land snails are dealt with, but these are probably sufficiently representative of the various types of dispersal-power in the animal kingdom. His method has been to make a list of the fauna of the whole region and to divide the species, genera, etc., into four groups: those with a predominantly western (Asiatic) distribution, those with an intermediate type of distribution, those with an eastern one, and those with a distribution of an 'indifferent' type. The frequency of the types on each island is then examined and other resemblances between the fauna of different islands or groups of islands are investigated.

A preliminary conclusion is to maintain the significance of 'Wallace's Line', running between the islands of Bali and Lombok. This line is not, as indeed Wallace admitted, a boundary between two distinct faunal regions. It is rather the western limit of many animals with an eastern type of distribution. Thus in Bali, amongst the 255 genera, the four types of distribution are in the proportions 128 : 3 : 5 : 115, while in Lombok the proportions are 70 : 5 : 10 : 117 (out of 202 genera). From Lombok eastwards, there is a gradual but regular increase in the number of eastern forms. A more general conclusion is that the islands west of Lombok form part of the Asiatic continental shelf, while New Guinea, etc., belong to the Australian shelf; between these areas lies a *labile* area where the relations of land and sea have long been unstable. The fauna of this unstable area is fundamentally Asiatic in origin, but in relatively recent times it has been invaded from the east. Forms with better developed powers of dispersal (birds and butterflies) tend to penetrate westwards more than less mobile forms (reptiles). Dr. Rensch considers (p. 298) that the facts in general support Wegener's application of his theory of continental drift to this region, though he would modify such details as the dates of separation very considerably.

Apart from the special study of the Malayan region, several points of the widest zoogeographical interest are raised. Thus the author considers what is known of the repopulation of Krakatau after the earthquake of 1883. This is used to show that birds, small snails, and small reptiles have a considerable advantage in dispersal over mammals, amphibia and larger snails and reptiles. Mere lack of power of flight is not necessarily a barrier. Again, he notes the frequency with which a few miles of sea appears to act as a barrier to bird species. He suggests that in these tropical conditions there is never a yearly shortage of food and that no species has any urge to leave its normal habitat.

In all zoogeographical speculation, one feels strongly the need for some independent line of evidence to support the theories. A sufficiently complex series of hypothetical land-bridges and inundations could explain all the known facts of distribution without being true. Supplementary evidence derived from fossils is probably by far the best type of support, but unfortunately such evidence is at present lacking in the Malayan region. In some cases, however, Dr. Rensch's suggested bridges and dates have been independently postulated by geographers.

The fauna of many of the islands is still, of course, imperfectly known, and Dr. Rensch indicates (p. 301) which are especially deserving of exploration. It may be suggested that one larger map on which all the islands mentioned were clearly marked would have been a very useful addition to the book.

O. W. R.

Plant Cytology

Die Pflanzenzelle

Vorlesungen über normale und pathologische Zytomorphologie und Zytogenese. Von Ernst Küster. Pp. xii + 672. (Jena: Gustav Fischer, 1935.) 34 gold marks.

THIS book embodies the main features in Prof. Küster's courses of instruction in plant cytology at Giessen as they have developed during the last fifteen years or so. It is therefore particularly interesting as reflecting the point of view of a school of botany from which a very definite individual contribution has been forthcoming during the period in question; at the same time, the book shows that the author has been at pains to keep abreast of modern views in a field where output of publications, of new terminology and of new theories has been at a maximum, though the progress of time may show that the actual addition of new facts has been proceeding rather more slowly.

Prof. Küster has himself been a pioneer in the study of pathological plant anatomy, and this experience gives a definite character to the book, in which anomalous behaviour of cells and both degeneration and regeneration phenomena are treated with unusual thoroughness, though at the same time with a welcome breadth of outlook.

The book is also a notable departure from most recent cytological texts in that almost equal space is given to the four sections upon protoplasma, the nucleus, the wall and cell development, whilst three rather less extensive sections deal respectively with plastids, with starch grains, crystals and other dead inclusions, and with vacuoles. Thus much less space is given to nuclear division phenomena than usual, whilst the chondriome and vacuome receive subordinate, if sympathetic treatment, in the sections that deal with plastids and the vacuole. The treatment throughout is balanced and critical, and when an extensive section of modern literature is dealt with rather summarily, as is the case with the mitogenetic hypotheses of Gurwitsch, the author briefly indicates the ground for his position.

Altogether, whilst probably no other plant cytologist would write a book with the same emphasis, that is obviously one of the reasons why the book should be welcomed by botanists generally, who will probably read it with profit, and notably such sections as the extensive one dealing with the contribution to our knowledge made by plasmolytic studies, where the author's own investigations give additional weight to the critical presentation of results. The full bibliographies to each section, including citations of papers published in 1935, add very considerably to the value of the work.

Nature and Functions of Soil Humus

Humus:
Origin, Chemical Composition, and Importance in Nature. By Prof. Selman W. Waksman. Pp. xi+494. (London: Baillière, Tindall and Cox, 1936.) 30*s*.

NO problems of soil science have proved more difficult than those concerning the nature and functions of soil humus. The early work of Sprengel and Berzelius yielded a long list of humic and other acids which are still discussed in textbooks and some scientific papers, even though it has long been shown that they are indefinite complexes greatly modified by the processes of extraction. Physical chemistry and microbiology have cleared up some of the problems involved in the acidity of peats and soils and in the decomposition of plant residues, but methods are still lacking for characterizing adequately the forms of humus in different types of soil.

The fundamental paradox is that, in the soil, cellulose is rapidly decomposed and humus is comparatively stable, whereas in the laboratory humus is readily oxidized under conditions in which cellulose is inert. It is now obvious that most of the steps in the decomposition of plant residues are effected by micro-organisms, and that the more stable products are colloidal complexes formed by the condensation of modified lignins from plants with protein degradation products from micro-organisms. Little progress has yet been made in unravelling the constitution of these complexes. In the past, loose analogies were too often drawn between the humus extracts from soils and the black messes so readily produced in a variety of organic syntheses.

Agricultural investigations have brought out a bewildering array of special circumstances in which soil fertility appears to be related to the amount and form of soil organic matter or in which farmyard manure remedies some defect. Thus, the steady decline in yield in fifty years of continuous cereals at Woburn (not at Rothamsted as given by Waksman on p. 199) was associated with a loss of one third of the carbon and nitrogen originally present in the surface soil. Soil drift in the Canadian prairies and erosion in many parts of the tropics are the results of systems of land management which destroy soil organic matter by cutting off the normal additions and intensifying through cultivation the losses by oxidation. Farmyard manure and crop residues return to the soil the major plant foods, a variety of 'minor nutrient elements', and decomposible organic matter which forms colloidal complexes with high absorptive power.

The processes of soil formation are so intimately linked with the growth of plants and the decomposition of their residues that the main subject matter of pedology might well be regarded as the ecology of humus. Already in forestry it is recognized that the natural humus type should determine the system of management, and it is almost certainly true that the proper husbanding of soil organic matter is the essential requirement for any stable system of agriculture.

The literature on soil humus is immense in volume and widely scattered, but much of it is poor in quality. A critical review to replace Wollny's book of 1897 was long overdue, and Prof. Waksman's monograph will be warmly welcomed by workers in agriculture and forestry and in the many pure sciences which bear on soil problems. It contains a bibliography of well over

1,300 papers, and a particularly useful historical summary which shows how confusion has arisen through the uncritical use of ideas, nomenclature and methods long after they had lost their scientific basis. The statement of recent work on the decomposition of plant products under experimental conditions should prepare the way for a much more cautious and systematic approach to the more difficult problems presented by the behaviour of plant residues in natural and cultivated soils. It is to be hoped that the book will reach such a wide audience that there will soon be an opportunity for a second edition at a greatly reduced price.

Dairy Science

The Chemistry of Milk

By Dr. W. L. Davies. (Monographs on Applied Chemistry, Vol. 10.) Pp. xii+522. (London: Chapman and Hall, Ltd., 1936.). 25*s*. net.

THIS book has been awaited with considerable interest by chemists and others working in a field much wider than that of milk production only. The extent of the interest is, indeed, a measure of the economic importance to-day of milk, not only as a substance for consumption more or less unmodified, but also as a raw material both for food products and in industrial processes.

It is perhaps not surprising that the literature of milk is vast. One would think it was the most important fluid in the world, to man as well as to the cow. It is a matter for some reflection that the literature of human blood, obviously the most important fluid to the human species, though wide and varied, is far less extensive than that of cow's milk.

Dr. Davies has wisely restricted the scope of his volume, which touches on bacteriological questions only quite incidentally. The book is what its title denotes, but it is more than a re-hash or a reconstruction of any previously existing book on dairy chemistry. The late H. Droop Richmond's invaluable volume may not be replaced by the newcomer, for it will always have great historical interest and a peculiar value owing to the fact that it was primarily the work of an analytical chemist, but the passage of time must necessarily give such a book more and more of a documentary and less and less of a practical value. Dr. Davies has taken the opportunity of bringing up to date all the literature surveyed in Droop Richmond's book, a process of deletion as well as of addition, and in so doing has entirely re-arranged the subject.

Part 1 of the book under notice discusses the composition of milk with particular relation to variations in composition and the causes thereof. Part 2 discusses each of the individual constituents of milk, from the type substances, butter-fat, lactose and casein, down to the 'minor' constituents, minerals, enzymes, vitamins and so on. Part 3 is devoted to the physical chemistry of milk, with a chapter on its coagulation, and Part 4 to the chemistry of milk processing, including particularly the technology of condensing and drying milk. Part 5 is, perhaps, not strictly speaking covered by the title of Dr. Davies's book, for it discusses the nutritive value of milk, both of its separate constituents and of milk as a whole. One can dismiss the possible irrelevancy of this inclusion in a book on chemistry, because of the importance of the subject and the interest of the survey.

Some minor criticisms may be permitted, such as the overlooking in Chapter viii of Bleyer and Kallman's work on the residual nitrogen of milk, although their work on lactochrome is mentioned. On the other hand, there is no reference to lactoflavin, the composition and synthesis of which have now been worked out, though they possibly had not been when Dr. Davies's manuscript was completed. Nevertheless, the position of flavin as an essential part of the vitamin B_2 complex was surely known at that time, and whey was its chief source.

One could, of course, make minor criticisms on many other points, especially on those where matters of opinion are involved. But surely Dr. Davies cannot maintain that commercial caseins should have a moisture below eight per cent; by far the greater portion of them have moistures between ten and twelve per cent, and generally nearer the higher figure. Dr. Davies does not, in my opinion, sufficiently stress the different properties of acid casein and rennet casein from the industrial point of view, and it is not made clear that they are quite uninterchangeable between the plastics industry and the adhesives industry (using this term in the widest sense). His figures for the moisture content of milk, whether spray dried or roller dried, are a long way out. Reasonable maximum figures for a good grade commercial full cream dried milk are 2·5 and 3·5 per cent respectively for the two types. Again, why does Dr. Davies state that "the conception of the analyst is that milk of low quality should not be offered for sale, such milk as an article of food being equivalent to adulterated milk" ? The view of the analyst—presumably Dr. Davies means the 'public' analyst—is that milk must conform to legal requirements, and Dr. Davies himself points out that legal requirements do not prevent the sale of milk of low quality, provided it is 'genuine', that is, comes uncontaminated from the cow.

The range of subjects mentioned in the course of the book is far larger than might be expected by those who only casually come into contact with the chemistry of milk and its constituents. Taking a few isolated random pieces of information, one may record the distinction between 'casein' and 'para-casein'; the analysis of the milk of the zebra, the llama and the porpoise, among other mammals ; the methods of estimating citric acid ; the nature of autoxidative changes in fats, and so on. Indeed, one of the weaknesses of Dr. Davies's book is that he has crowded into it so much recorded information that he has left himself no time or space to evaluate it critically, and much of it badly needs this evaluation. The many detailed bibliographies at the end of each chapter, however, enable the reader to turn to the original sources and make this evaluation for himself. The book is made still more useful by an alphabetical author index before the subject index at the end.

This book is so important, and must so soon go into another edition, that the reviewer feels, in all friendliness, obliged to urge upon Dr. Davies and the publishers to make a new edition the occasion for careful revision. There is evidence of inefficient proof reading. Some of the undetected errors are trivial, but one can scarcely pass over the description, on p. 96, of β-lactose as "β-glucose-β-glucoside". Again, on the next page, it is stated that Hockett and Hudson's new compound constituted "the first instance for lactose to crystallise out in the anhydrous form". The statement should have been made to apply, of course, to α-lactose only, since β-lactose always crystallizes without water of crystallization.

It has, moreover, to be admitted that Dr. Davies possesses an unfortunate and rather inelegant style. This is shown in, for example, his definition of iodine value as "the percentage of iodine with which the unsaturated acids of the fat can combine". One sees what Dr. Davies means, but he has not said it. There is a sentence towards the end of p. 80 that is, at any rate to the reviewer, almost meaningless, and this is not the only example.

The fact remains that Dr. Davies's compilation is very valuable, and would be invaluable were it readable, which in places it is not, owing to his curious handling of the English language. In a sincere wish to increase the value of this book to workers in many branches of science and technology, and in the desire to assist Dr. Davies in maintaining the high reputation that is already rightly his in the research field, I would urge upon him to enlist the assistance of some of his colleagues at Reading for a thorough revision of this book on the literary side.

A. L. BACHARACH.

The Field of Inorganic Chemistry

Inorganic Chemistry

By Niels Bjerrum. Translated from the third Danish edition (1932) and brought up to date and adapted to English conditions in collaboration with the author by R. P. Bell. Pp. x+317. (London : William Heinemann, Ltd., 1936.) 7*s.* 6*d.*

It is seldom that any real enthusiasm can be aroused by an introductory chemical textbook. After the novelty of the 'ultra-humanized' book, introduced a decade or more ago, had worn off, there appeared imitations with varying degrees of merit, and differing mainly in the order of presentation of conventional matter, just as previous to them a line of monotonous uninspired productions had challenged the keenness of generations of beginners. Prof. Bjerrum's volume does not essay to initiate a further revolution ; it strives after no sensational effects, but unostentatiously and by a masterly treatment of its subject matter embodies all the qualities of a really first-class text-book. For its modest size, its special strength is in its handling of physical and theoretical aspects and developments. There are few who would fail to endorse the opinions expressed in the foreword by Prof. Donnan, who states that it is the finest introduction to modern chemical science that he has read, that there is no fundamental aspect of that vast field as it exists to-day that the book does not explain and illustrate in a clear and logical manner, and that its adoption in every English-speaking seat of learning would result in a marked improvement in the average standard of chemical knowledge.

After a short introductory chapter, the atomic theory with its practical aspects and ramifications is treated in the widest sense, embracing solutions, crystals, kinetics and valency. The non-metals are then dealt with in natural groups; a special feature, however, is that each group is followed by an adequate section on chemical change, each section being the one most suitably illustrated from the element-group preceding it. Thus hydrogen is followed by velocity and equilibrium in the formation of water, the halogens by velocity of chemical reaction, the sulphur group by a comprehensive survey of the modern theory of acids, bases, ionization and reactions in solution, the nitrogen group by the laws of chemical equilibrium, and the carbon group by thermochemistry and fuels. Then come the light metals with radium and radioactivity, the periodic system, atomic structure and electrochemical series; lastly, we have the commoner heavy metals in their appropriate groups. With copper and silver are considered the complex compounds and the general theory of complex ions, electrovalency and the nature of chemical linkage.

Practical aspects and applications of chemistry are interwoven throughout the whole text. It would perhaps be hypercritical to complain that there are no photographs and only seventeen line diagrams, including graphical plottings, and that deuterium is no more than mentioned and nothing is said about heavy water.

As a result of the inclusion of far more detailed physical chemistry than is found except in a large treatise or special text-book, we have a most up-to-date and useful survey of that branch of the science; the section on the modern theory of electrolytes is particularly worthy of note, covering as it does about forty-five pages and being work with which the author and his collaborators of the Danish school of physical chemistry are so closely associated. The book should be a source of inspiration to the post-novitiate student and one of interest and instruction to the more hardened scientific veteran. Binding, printing and production are in keeping with the high standard of the text.

N. M. B.

Structure Factor and Electron Density Formulæ

Simplified Structure Factor and Electron Density Formulæ for the 230 Space Groups of Mathematical Crystallography

By Dr. Kathleen Lonsdale. (Published for the Royal Institution.) Pp. vii+181. (London: G. Bell and Sons, Ltd., 1936.) 10*s*. net.

THE intensity of an X-ray crystal reflection is governed by many factors, such as the state of perfection of the specimen and the electronic structure of the component atoms, but chiefly by the relative arrangement of the atoms in the unit cell. The resultant amplitude obtained by combining simple sine waves emanating from each atom in the structure is known as the geometrical structure amplitude. Dr. K. Lonsdale has carried this summation over the co-ordinates of the general positions in which the atoms lie ("equivalent points") for each of the 230 space groups of mathematical crystallography. The general formulæ she has already given in the "International Tables for the Determination of Crystal Structures" (see NATURE, 137, 927; 1936), but in the present work these equations are reduced to forms in which they can be applied directly for any given combination of indices. In addition, the converse formulæ, in which the electron density at any point is expressed as a Fourier series, are given in convenient form, the summation here being taken over the eight quadrants of the reciprocal lattice, so that only positive values of the indices *hkl* need be considered, if the axes are orthogonal. For non-centrosymmetrical structures, the way in which the phase constants vary in the different quadrants is also given in every case.

We must congratulate the author on the completion of this intricate and beautiful piece of work. It will prove of inestimable value to all those engaged in quantitative X-ray analysis of the solid state, and its necessity will become more and more apparent as the methods of investigation improve and it becomes possible to make more rapid comparisons between one structure and another often belonging to an entirely different space group. The task of deriving these complicated relations from first principles each time soon becomes a serious handicap. Attention should be paid, however, to the warning given by the author as to the necessity of understanding the basis of the calculations before attempting to apply the tables in special cases.

The photographic method of reproduction from the original manuscript ensures freedom from misprints, and has the further welcome result of making the price very moderate for a work of this nature. We envy Mrs. Lonsdale her ability to produce such a manuscript, that all can read!

J. M. ROBERTSON.

A Programme for Astrophysics

Theoretical Astrophysics:
Atomic Theory and the Analysis of Stellar Atmospheres and Envelopes. By S. Rosseland. (International Series of Monographs on Physics.) Pp. xix+355. (Oxford: Clarendon Press; London: Oxford University Press, 1936.) 25*s*. net.

THE author of this book is well known as the professor of astronomy in the University of Oslo. It is evident that the same broad outlook upon the future of his science that led him to found the Institute of Theoretical Astrophysics at Oslo, with its associated publication *Astrophysica Norvegica*, has inspired him also in planning this volume.

The first few chapters give a logically developed account of atomic theory, treated by wave mechanics approached from classical dynamics via statistical mechanics. It is taken as far as the theory of atomic multiplets, and followed by a short account of the quantum theory of radiation. So it provides in outline a necessary and sufficient basis in general physics for almost all the astrophysical theory which follows.

The central part of the book is naturally devoted to the theory of stellar atmospheres. Starting from the theory of propagation of radiation in an atmosphere, and the formation of the continuous spectrum, it passes on to the treatment of line-widths and total intensities. A special feature is the account taken from the outset of the possibility of cyclical atomic transitions between more than two quantum states. Prof. Rosseland was himself the first to realize their significance in his well-known theory of bright lines in stellar spectra, and they have lately gained new importance in regard to the troublesome question of the central intensities of absorption lines. This theory is then linked on to that of thermal excitation and ionization in stellar atmospheres, which is specially associated with the names of Saha, Fowler, and Milne. By giving a simple unified rational interpretation of the whole sequence of stellar spectra, it probably still ranks as the most remarkable success in the application of atomic physics to astronomical observations. The effects of rotation, and of electric and magnetic fields, on the form of stellar lines are next considered. The occurrence of molecular bands in the spectra is also thoroughly discussed.

The last part of the book deals with the theory of stellar material lying outside the normal atmospheres. It proceeds from a consideration of the solar chromosphere and corona to the extended envelopes of some giant stars, then to gaseous nebulæ, and finally to the cosmic cloud. These all present new problems of mechanical and radiative equilibrium, amongst the latter being various intensely interesting questions connected with the occurrence of 'forbidden' lines.

The author's method in tackling any problem is first to describe clearly the *general* physical theory and the *general* mathematical methods that are required. In dealing with applications, he is, in this book, more concerned with key ideas, and with a careful statement of the assumptions and restrictions that have been made, than with details of results. This treatment will make the book particularly valuable to anyone beginning research in astrophysics. In the first place, it will put him in a position to refer intelligently to works of reference on physical subjects of the type of Fowler's "Statistical Mechanics" or the "Handbuch der Physik". In the second place, it will enable him to read the most recent work on the branches of theoretical astrophysics here treated, with a clear understanding of what has led up to it, and of the technique employed. Also the book will be welcomed by mathematical physicists wishing to gain an adequate idea of this field of application of their work.

The book has one characteristic which some readers may judge to be a deficiency. The astrophysical applications are in many cases left off at a seemingly unsatisfactory stage, and not completed by working out detailed theoretical results suitable for crucial observational tests. But this is apparently done by design. For, in spite of the almost startling successes of the subject, surveyed in the masterly introduction to the present volume, there is probably no part of it that will not repay fresh investigation using more powerful mathematical methods or more general physical models. The hope that this will be done, no less than that fresh problems will be attacked, is evidently behind the prefatory remark: "The aim of this work is to formulate a programme of theoretical astrophysics. . . . A second volume is planned to give a similar view of the internal structure of the stars". Prof. Rosseland's attractive presentation of his programme should draw many recruits to the promising task of attempting it.

W. H. McC.

The Theory of Differential Equations

Introduction to the Theory of Linear Differential Equations
By E. G. C. Poole. Pp. viii+202. (Oxford: Clarendon Press; London: Oxford University Press, 1936.) 17*s.* 6*d.* net.

SINCE Newton and Leibniz began to study differential equations in the seventeenth century, mathematics has made great strides. Though the creative mathematicians have mainly been inspired by the art of their subject rather than by the prospect of its useful applications, yet the demands made by the rapid progress of science have been responsible for a considerable amount of research. Much of this has been devoted to differential equations, for herein lies primarily the mathematical basis of applied science, notably physics and engineering. Unfortunately, however, most practical equations cannot be solved in finite terms, so that resort has to be made to approximations. Even Newton himself realized this difficulty and tentatively applied power-series, but before such a method could be reliably applied, it was necessary to show, not only that the power-series was valid within specified boundary conditions, but also that a solution to the given equation actually existed. It was not, therefore, until Cauchy discriminated between analytic and non-analytic systems and gave rigorous existence theorems for each type that any material progress was made.

Of the many types of equation, that which occurs most frequently is the linear form and, as a consequence, much has been written on separate branches of the relevant theory. Dr. Poole's "Introduction", the preface of which forms the basis of the above sketch, deals with this type and incorporates a considerable amount of noteworthy research in a single volume. The text, running into ten chapters, may be divided roughly into two parts. The first part, consisting of the first five chapters, deals mainly with the properties common to most linear equations; the second part—Chapters vi–x—is devoted to detailed discussions of the well-known equations of Gauss, Laplace, Lamé and Mathieu.

Among the general properties may be specially mentioned the powerful operational calculus of Heaviside, with its important application to equations with constant coefficients, and also, the principle of invariant factors, so essential to the Fuchsian theory. In the chapter on equations with uniform analytic coefficients, the interchange of solutions around a circuit is well illustrated by Euler's homogeneous equation and the equivalent system of linearly independent solutions—the Hamburger set—derived from Jordan's canonical transformation. Thomé's inductive proof of Fuchs's condition for a regular singularity is also given, together with Birkhoff's direct proof of the sufficiency of the conditions. The final chapter of the section on general properties is concerned with regular singularities, and includes a rigorous treatment of formal solutions in power-series.

Chapters vi and vii begin the detailed examination of some particular equations and are devoted to the theory of Gauss's, or the hypergeometric, equation. The relation between this and Riemann's P-equation is clearly exhibited and the existence of Kummer's 24 series-solutions proved. The discussion then passes to Schwarz's problem and conformal representation. The special cases of the dihedral, the octahedral, the tetrahedral and the icosahedral equations are of particular interest. Chapter viii deals with Laplace's transformation of the generalized equation with constant coefficients. This includes the theory of Kummer's first and second confluent hypergeometric equations with integral representations of their solutions. Then follows, in Chapter ix, the derivation of Lamé's equation and the relevant theory introducing Weierstrassian elliptic functions, with Halphen's transformation and Brioschi's solutions. The chapter ends with a brief discussion of Picard's type of equation in which the coefficients are uniform doubly-periodic functions.

The final chapter gives an account of Mathieu's famous equation which arose in a problem on a vibrating elliptical membrane. The particular solutions, known as Mathieu functions, are soon introduced, but, owing to the difficulty of finding a solution to the general form, only the equation which arises in celestial mechanics is considered. The theory concludes with an account of the solution of Lindemann and Stieltjes, which is modelled on the Hermite-Broschi treatment of Lamé's equation.

The equations of Bessel and Legendre have not been discussed in detail, for, as the author points out, "there are so many admirable accounts of them in English suitable for students of every grade".

Each chapter contains a number of important and useful examples, many of which are additional theorems taken from original papers. A valuable bibliography is also provided for further reading.

The book is designed for senior undergraduates at Oxford, but it may be confidently recommended to every mathematician interested in the very important study of differential equations.

F. G. W. B.

The Growth of Ancient Science

Histoire des sciences : Antiquité
Par Pierre Brunet and Aldo Mieli. (Bibliothèque scientifique.) Pp. 1224. (Paris : Payot et Cie., 1935.) 200 francs.

THE history of science claims a legitimate place in the organization of research and learning on the ground that it gives a faithful account of the development of positive knowledge with reference to the intellectual atmosphere of the various periods of civilization. It is not merely as an outline of the progress of thought and technology, but rather as a critical exposition of the chequered career of scientific thought, that the history of science has now secured recognition as an important and useful branch of knowledge and study. Of this conception of the history of science, an excellent illustration is given by the present work, which covers the origin and growth of ancient science.

In spite of its comprehensive title, this work deals almost exclusively with classical antiquity, though three of the opening chapters (pp. 38–112) are devoted to those civilizations which are claimed to have a direct influence on Greek and Roman thought and technology. It may be said, however, that a mere juxtaposition of the Eastern civilizations with that of the Greeks does not illustrate sufficiently the influence of the former on the latter. It is true that we possess little direct evidence of the possible filiation of this influence. But there is no reason why a discrimination should be made in favour of the Egyptian and Assyro-Babylonian civilizations.

There have been numerous and sometimes prolonged contacts between Greece, on one hand, and Persia and India on the other ; consequently, it is only fair to discuss, on the evidence we possess, the probable influence on Greece of all those races and civilizations with which Hellenism came into contact. As a matter of fact, this should be one of the most important tasks of modern research in this field of study. The authors of this work recognize the importance of this task, and they propose to deal with it more fully in another volume. In a lengthy note on p. 330 they indicate that the influence of Persia and India on Greece is not so great as is sometimes thought ; and they believe that if much of what is said of the antiquity of Indian science is discounted, it will be found that Greece may have influenced Hindu thinkers much more than is commonly admitted. The importance of this question is such that what they have to say on the matter in their forthcoming volume will be awaited with keen interest.

Faithful to their method of adhering strictly to original documents, the authors give a rather short account of the Pythagorean School. Similar reasons led Prof. Loria to dismiss summarily, in his "Storia delle Mathematiche", the claims put forward in favour of the importance of Pythagorean mathematics. But Sir Thomas Heath felt himself justified in giving, in his "History of Greek Mathematics", nearly one hundred pages to Pythagorean theories, for the evaluation of which he also uses later writers such as Nicomachus, Iamblichus and Theon of Smyrna. The truth may lie somewhere between these two positions. Nevertheless, the natural philosophy at least of the Pythagoreans (p. 428) could have been treated more fully in the present work, by making a judicious use of the testimonies of Plato and Aristotle and of other writers.

Of the controversial questions about which a straightforward opinion of the authors is given, we may quote Aldo Mieli's view of the personality of Socrates, whom he considers to be the last of the Sophists, or rather, as he puts it, a "Sophiste manqué", afterwards idealized by his disciples (p. 200). Contrary to the general belief, Aldo Mieli thinks that the influence of Socrates on science is more destructive than anything else, because he diverted the attention of the mind from the study of external phenomena to introspective or moral considerations. Again, the authors maintain that the study of Plato belongs to literature and philosophy rather than to science, his views on various scientific subjects being more speculative than positive.

A more generous attitude is taken towards Aristotle, because of his empirical attitude of mind ; and though the physical doctrines of the Stagyrite have been long ago discarded by science, the spirit of his inquiries still remains a fundamental characteristic of scientific research. Moreover, the results obtained by Aristotle in the field of biology are of the greatest importance in themselves as well as for the history of science. All these points are adequately developed by the authors, who do not seem to share the opinion expressed by Prof. F. Enriques in his work "Il Mondo Antico", where he accuses Aristotle of having suffered from an inferiority complex and from an exaggerated 'professorial' attitude of mind.

An important part of the present volume deals with the Golden Age of Greek science in the Alexandrine period. In the field of pure mathematics, Euclid, Archimedes and Apollonius are treated with the prominence they deserve. The study of the works of Archimedes is far from being complete, and the authors believe that much could be done by using the available Arab manuscripts. In a lengthy note on p. 387, they explain the meaning of the famous "Method" of Archimedes as involving the notion of "integral" and of "static moments" considered as proportions and not as products of a distance by a force. It is thus suggested that this Method, which was known in the Middle Ages, has influenced the conceptions of Cavalieri and the genesis of the calculus.

The astronomical views of Heraclides and Aristarchus, and their bearing on the heliocentric view of the universe, are summarized and contrasted with the doctrine of the homocentric spheres developed by Eudoxus. So also are the remarkable labours of Hipparchus, who improved the theory of the Epicycles and used trigonometrical methods in astronomy, and of Eratosthenes, the founder of scientific geography. A good account is given of Ctesibius, Philo and Heron, the most representative engineers of classical antiquity. Of the later astronomers, Ptolemy is given fifty pages, in which a summary of his works is followed by helpful appreciations and criticisms from the authors. Interesting additions to the traditional exposition of Ptolemy are the two chapters on optics and acoustics, in which an adequate account is given of the methods and views of the ancients concerning these important subjects. The exposition of Greek mathematics closes with an analysis of the writings of Nicomachus, Diophantus, Pappus and Proclus.

The development of ancient medicine is outlined with great skill and understanding in Chapters viii, xxix, xxxvi, xliv, xlv and liii. The Hippocratic writings, the Alexandrine physicians, the controversies about Celsus, the various schools of medical theory, the remarkable works of Galen and the decline of medicine during the Byzantine period, are considered in turn and illustrated with long extracts from the original texts. The pharmacological views of Dioscorides are treated in a separate chapter. Chemistry is given only one chapter, near the end of the present work ; in this connexion, an interesting passage is quoted from a "Lesson of Comarios to Cleopatra" about the fabrication of gold.

If the Romans made negligible contributions to pure science, their practical mind asserted itself in their interest for applied science. Agriculture and husbandry, engineering and public works, navigation and military science, geography and meteorology, biology and medicine, owe a great deal to the genius of the Romans. This debt is very ably outlined in the present work in the several chapters dealing with the development of these subjects during the Greco-Roman period. The architectural theories of Vitruvius, the encyclopædic work of Pliny, are thus discussed side by side with the geographical writings of Strabo, and the tidal hypotheses of Posidonius. After a brief mention of the encyclopædists of the beginnings of the Christian era, the authors bring us to the threshold of the Middle Ages.

The volume contains a mass of material of scientific, historical and controversial interest—so much, indeed, that there is a risk that the reader may have difficulty in following the thread of the story. The authors are at great pains, however, to explain carefully the various problems raised in the light of the available texts, and to discuss conflicting opinions about them in a wealth of footnotes. The views expressed are illustrated and supported by nearly three hundred textual quotations from more than eighty original sources ; and a number of passages have been translated by the authors themselves. A comprehensive index, two synchronical tables and a critical bibliography of twenty-five pages add to the practical and scholarly value of this important work.

THOMAS GREENWOOD.

Short Notices

Archæology and Anthropology

The Law and the Prophets

By H. Peake and H. J. Fleure. (The Corridors of Time, Vol. 9.) Pp. viii+188. (Oxford: Clarendon Press; London: Oxford University Press, 1936.) 5*s*. net.

In each succeeding volume of "The Corridors of Time", the authors have sought to epitomize the salient characters of a period, as well as mark the cultural advance recorded. In electing to close the series with "The Law and the Prophets", they indicate that they see the transition from archæology to history, not so much as a matter of written record, as the dawn of abstract thought and the initiation of a concept of godhead, which transcends the tribalized or local deity. This is a logical scheme, but in practice it is apt to leave ragged edges.

Broadly speaking, this volume covers the last millennium B.C., coinciding, however, more or less with the Iron Age, rather than with any absolute span in term of years. It opens with the rise of the Scyths, passes then to Assyria, China of the Chou Dynasty and the philosophers, India, where the racial problem is further discussed in the light of the last census report, the rise and fall of the Jewish kingdom, Persia, Greece and the rise of Greek philosophy, and the Iron Age of Italy, of Central Europe and finally of the British Isles. As the authors have been constrained by their plan to deal very briefly with a vast body of material, which in large part is historical, their method of treatment has been cramped, and they have been able to devote too little space to the archæological argument, in which, as is shown in the admirable, if brief, summary of the results of latest research in the British Isles, their power of acute and suggestive reasoning most frequently illuminates the evidence.

A welcome announcement states that a supplementary volume will deal with the processes of racial and social evolution of man in general terms.

Bitumen and Petroleum in Antiquity

By R. J. Forbes. Pp. vi+109. (Leiden: E. J. Brill, 1936.) 2 f.; 5*s*.

Knowledge of the technology of bitumen in antiquity has been considerably extended by the recent excavations at Ur and elsewhere in Mesopotamia. Mr. R. J. Forbes, though a technical expert and not an archæologist, has made a comprehensive survey of the archæological and literary sources for the use of bitumen in ancient times, and discusses fully the information relating to the character, sources and uses of the material to be derived from this evidence.

Although known and used from very early times, the importance of bitumen and oil in industry and commerce is a modern development, their place having been taken by pitch produced from wood from Roman times onward, except in the manufacture of 'Greek fire', of which the use, it was agreed among the nations in medieval times, was "too barbarous" for war. This oblivion, which became more or less complete in the Middle Ages, Mr. Forbes attributes to the fact that not only were the ancients impressed by the dangers of handling the material, but also the principal sources of supply lay outside the bounds of the Roman Empire in the eastern sector of the Fertile Crescent, and more especially on the eastern side of the Dead Sea and in Mesopotamia.

Mr. Forbes, on the whole, agrees with the view that the use of bitumen by the Egyptians in embalming is late and not so extensive as was once thought. At the same time, he points out that the importance attached by the Egyptians in Ptolemaic times to control of the area in Palestine in which it occurred, must be regarded as significant. His examination of the uses of bitumen in building construction in early Mesopotamia and at Mohenjo-daro will afford valuable guidance to field archæologists.

Biology

Rhododendrons and Azaleas:

their Origins, Cultivation and Development. By Clement Gray Bowers. Pp. xiv+549+40 plates. (New York: The Macmillan Co., 1936.) 42*s*. net.

As announced in the preface, this book is concerned with the practical use of rhododendrons and azaleas in North America and elsewhere. In England much valuable experience has already been gained with the genus, and made public by the Rhododendron Society and Rhododendron Association. Full use of this information has been made by Mr. Bowers and he is to be congratulated on having provided a very useful compendium on the genus, especially for American readers. His chapter on the behaviour of new introductions in America should be of special interest to growers in Great Britain, where diversities of climate are not nearly so great.

Inside the covers of the book are two highly decorative maps of that part of the Old World and of North America wherein rhododendrons are found, the numbers in red referring to the geographical regions mentioned in the text. It is a pity, however, that the distribution of the outlying species, *R. Lochæ*, in Queensland should have been omitted, the presence of this species on a remote mountain being of considerable phytogeographical interest.

The coloured illustrations are very poor and not worthy of the book. Indeed, they seem more suitable as designs for wallpaper-panels. The black-and-white figures, however, though crude, often give quite a good impression of the species, which may sometimes be recognized by anyone who already knows them well. The few photographs are mainly of general views in gardens and are very well reproduced.

The large bibliography will be useful to most readers and is divided into (1) general references, (2) historical, (3) culture and propagation, (4) physiology, etc., (5) hybridization, etc., (6) pathology and insect pests. J. H.

Les conceptions modernes de l'hérédité

Par Prof. Maurice Caullery. (Bibliothèque de Philosophie scientifique.) Pp. 312. (Paris: Ernest Flammarion, 1935.) 15 francs.

THIS book gives a fairly adequate account of the physical basis of heredity and of the more conventional aspects of genetics. The general treatment is on the whole satisfactory, but scarcely original. Unfortunately, many of the more important modern advances are omitted. There is no discussion of auto- or allo-polyploidy, of the evolution of dominance, or of the gene-complex. The physiology of sex-determination, and the whole subject of genetic physiology, is also omitted. The treatment of cell-division is entirely out of date: no attempt is made to modify the older views of it in accord with the work of Bělař, Darlington and the modern school of cytologists. On the other hand, Stern's cytological proof of genetic crossing-over is explained in a helpful manner.

There is a somewhat inadequate index, from which all names of authors are omitted. The references are scattered throughout the book, at the foot of the pages on which they are quoted. This is an extremely inconvenient system; they should be collected at the end, when they ought to form a useful bibliography. E. B. F.

Chemistry

A Text-Book of Organic Chemistry

By the late Dr. Julius Schmidt. English Edition by Dr. H. Gordon Rule. Third Edition, revised and extended. Pp. xxiv+865. (London and Edinburgh: Gurney and Jackson, 1936.) 25s. net.

THE appearance of a third English edition of Julius Schmidt's text-book bears witness to a steady demand for this work by advanced students of chemistry and biochemistry. This is not surprising, as the choice of comprehensive text-books of advanced organic chemistry in the English language is strictly limited. The work under notice deserves commendation as providing a coherent and well-documented background to the numerous monographs and series of lecture-notes with which the present-day student reading for honours in this expansive subject is hedged about. Although it has grown from 798 to 865 pages since 1926, this text still remains between two covers. This is a distinct merit; for, as a modern Dean Swift might write, whoever can reduce two volumes of an advanced organic chemical text-book into one deserves better of the honours student than the whole race of Beilsteins and Richters put together.

The new edition is considerably in advance of the last German edition of 1929, as on account of the death of Prof. Schmidt in 1933 no later German issue has been made. Dr. Rule has added materially to the value of his English text by including accounts of recent advances in the biochemical zone of organic chemistry (polysaccharides, sterols, bile acids, vitamins, hormones, natural colouring matters, etc.); the physical zone, also, has received its share of attention through the treatment of such topics as recent work on the Beckmann transformation, dipole moments, and dissymmetric allene derivatives.

It may be suggested that a fuller reference to the subject of strainless rings would be of use. J. R.

Recent Advances in Organic Chemistry

By Prof. Alfred W. Stewart. Vol. 2. With the addition of Part 2, by Dr. Hugh Graham. Pp. xiv+519+2 plates. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1936.) 21s. net.

THE reissue of the sixth (1931) edition of Prof. Stewart's well-known work contains a new supplement of four chapters by Dr. Graham, dealing with the bile acids and sterols (28 pp.), the cardiac aglucones (vegetable heart poisons) (7 pp.), the hormones (23 pp.), and the vitamins (19 pp.). Separate name and subject indexes are provided for the supplement. Dr. Graham has given a judiciously selective account of the important advances in these fields of work, so that in its extended form the book will continue to render valuable service to advanced students and research workers in organic chemistry and biochemistry. That progress during the past few years in the common domain of these two regions of chemical science has outstripped the most sanguine anticipations of the last decade is a reflection which must occur forcibly to readers of this supplement, with its review of so many spectacular achievements.

Engineering

Dielectric Phenomena in High Voltage Cables

By Dr. D. M. Robinson. (Monographs on Electrical Engineering, Vol. 3.) Pp. xii+173. (London: Chapman and Hall, Ltd., 1936.) 15s. net.

THE economies effected by the use of very high voltages when transmitting electric power have led to its rapidly increasing adoption, but the higher the voltage the greater the number of breakdowns of the transmission cable. In electric supply an interruption of this nature is most serious; so expensive and elaborate tests in specially constructed laboratories are being carried out by cable manufacturers on the wrappings which surround the cables (the sheath).

In some cases the breakdown leaves a clean radial hole between conductor and sheath. In others, scorched and brittle papers are found particularly in the inner portions of the dielectric. Often they leave tree-like or fern-like patterns accompanied by dry patches where scarcely any free impregnating oil remains. The early investigators were baffled by the complexity of these breakdowns and concentrated their attention on the losses which occurred during a life test of the cable. Mathematical methods which assume that the sheath is homogeneous and that there are no 'voids' in it are only of limited use. In the book under notice, Dr. Robinson shows that visual examination has succeeded where external electrical measurements have failed. The work was carried out in the Research Laboratories of Callender's Cable Co.

The Design of Reinforced Concrete Structures

By Prof. Dean Peabody, Jr. Pp. ix+457. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1936.) 20*s.* net.

THE wider aspects of design are dealt with in detail by Dean Peabody in his book "The Design of Reinforced Concrete Structures". Theory is introduced so far as is necessary to develop the methods of calculation employed and to elucidate the force systems dealt with in the course of his subject, which includes the practical design of slabs, rectangular and tee beams, columns, footings and retaining walls, statically indeterminate structures and concrete arches. The numerous illustrative problems which have been fully worked out will be of especial value to the student. J. A. C.

Miscellany

The Paradise of Fools:

being an Account, by a Member of the Party, of the Expedition which covered 6,300 Miles of the Libyan Desert by Motor-Car in 1935. By Michael H. Mason. Pp. 282+23 plates. (London: Hodder and Stoughton, Ltd., 1936.) 15*s.* net.

ALTHOUGH this expedition into the Libyan desert, with Mr. Kennedy Shaw as leader, undertook scientific investigations, its primary function was exploration; and to the author of "The Paradise of Fools", in which it is described, it was mainly "a joyous adventure". The expedition, of which Mr. Shaw gave accounts in *The Times* during August 1935, and later before the Royal Geographical Society, covered by motor-car altogether six thousand three hundred miles, of which some three thousand were in country previously unexplored. Starting from Cairo, the cars travelled along the Nile to Assiut, then south-west to the Gilf Kebir plateau and then by devious ways from oasis to oasis to El Fashir, about four hundred miles west of Khartoum. They returned, mainly westward of their outward route, by way of the Selima oasis, through the Great Sand Sea between Gilf Kebir and Siwa northward to the Mediterranean.

The author's keenest interest lies in the desert, with all its attractions, less apparent perhaps to other travellers, as well as its dangers. The latter have by no means vanished with the coming of the motor-car, although they have changed their nature, and hardships have diminished. As hunter, Mr. Mason, when not engagingly concerned with the desert and incidents by the way, gives his attention mainly to the observation of animal life, more especially in its relation to water supply. Scientific results, however, are recorded in appendixes and a large-scape map. Of these results, the most noteworthy were archæological. The expedition secured some remarkable evidence of the activities of early man in the form of rock-drawings, pottery and the like, as well as skeletons of early man himself, of which some details have already appeared in NATURE (137, 159; 1936).

American Martyrs to Science through the Roentgen Rays

By Dr. Percy Brown. Pp. xv+276. (Springfield, Ill., and Baltimore, Md.: Charles C. Thomas; London: Baillière, Tindall and Cox, 1936.) 16*s.*

THIS work contains short and vivid accounts of the life and work of twenty-seven men and one woman—Mrs. Elizabeth Fleischman Ascheim—aged from thirty-five to seventy-seven years at the times of their deaths, who as doctors or technicians in the United States contracted severe X-ray dermatitis and cancer, and died after many years of suffering and operations in the form of skin grafting or amputation.

Among the most eminent of these martyrs were Clarence Madison Dally, who with his brother Charles did valuable work in the development of the various types of X-ray focus tube; Louis Weigel, who introduced an adaptation of the Wheatstone stereoscope, and invented a tube holder; Wolfram Conrad Fuchs, inventor of an electrolytic interrupter; Rome Vernon Wagner, inventor of the mica plate static machine; and his brother Thurman Lester Wagner; Charles Lester Leonard, a pioneer in urinary rontgenology and a prolific writer; Walter James Dodd, who occupies the same place in early American radiology as does Rontgen in the annals of German science; Eugene Wilson Caldwell, inventor of the liquid interrupter and of a stereo-fluoroscopic apparatus as well as of a practical method for examining the accessory sinuses of the nose; Frederick Henry Baetjer, author of important papers on the X-ray diagnosis of aortic aneurism and bone tumours; Francis Le Roy Satterlee, who made valuable contributions to dental radiology; and William Krauss, a pioneer in the therapeutic use of X-rays.

The text is freely interspersed with portraits and illustrations of röntgenological apparatus and accompanied by bibliographical references. A glossary for lay readers is appended.

A Parson in Revolt

By Joseph McCulloch. Pp. 174. (London: Nisbet and Co., Ltd., 1936.) 3*s.* 6*d.* net.

MR. MCCULLOCH is a young clergyman who delivered a broadcast talk in the "Youth Looks Ahead" series about a year ago. One of the thousand letters received by him as a result of his broadcast is printed in the author's preface to the volume before us. It sheds a clear light on the attitude of many who have a strong desire to satisfy their religious instincts, but do not find the Church of much use to them. "The real difficulty of our time," says Mr. McCulloch, "is in the approach to religion. The modern reaction is first an intellectual quarrel, then an attack on the institution, and third an expression of a genuine desire for God." But Mr. McCulloch pleads that it is "fundamentally topsy-turvy to attempt to build up a religion by starting with a search for one which is intellectually watertight". This is doubtless the case in so far as the religious need is not *primarily* an intellectual, but an emotional one. At the same time, a religion that is not "intellectually watertight", or at least reasonably so, is not of much use to anybody. Such a religion can only be a more or less deceptive fantasy, and cannot be relied on in a crisis.

The trouble with institutional religion as it exists to-day is that it does not take the claim for "intellectual watertightness" nearly seriously enough. Merely to bring the technique of worship up to date, and to scrap the parochial system (as Mr. McCulloch suggests), is just to scratch the surface of the problem. Beautiful and inspiring worship, and efficient organization, avail nothing if the religion stresses as important beliefs which are not historically or scientifically true. Yet Mr. McCulloch has written an honest, stimulating book. J. C. H.

Physics

Electrical Measurements in Principle and Practice

By H. Cobden Turner and E. H. W. Banner. Pp. xiv + 354. (London: Chapman and Hall, Ltd., 1935.) 15*s*. net.

THE always inadequate literature of electrical measuring instruments is notably strengthened by this addition. The frontispiece in itself is worth having, though it merits printing on three separate pages normally oriented in place of the single much folded sheet, which demands some proficiency in acrobatics for its full enjoyment. The treatment of the measuring instruments of power-engineering and of audio-frequency work is in general satisfactory; that of the more fundamental work, and of oscillographic work, is not so good; while the treatment of radio-frequency measurements is definitely amateurish.

Local patriotism and the camera have combined to weaken the balance and usefulness of the work as a whole. The predominance of Lancashire does not extend so far into the instrument field as the proportion of "Salford" illustrations suggests. Photographs, without the inclusion of the invaluable foot-rule, are much less useful to the reader than are line diagrams. The authors have allowed the sales and publicity men to unload on them an undue share of their facile material, as, for example, on p. 241, a "Valve Oscillator. Mains All-Metal Type". The learned judge might, with more reason than usual, ask "What is an all-metal oscillator?" Whether he might advantageously be invited to turn his attention to p. 143, "experience in the supply of testing instruments to the Government Services has produced robust instruments able to withstand the maximum of rough handling", is a high-politico-legal problem.

The definition of a galvanometer (p. 109) is not good; the reference to oscillographs on the same page is worse. A galvanometer is not necessarily sensitive; it is of its very essence that it does not, directly, "measure" D.C. or A.C.; oscillographs are not merely "a form of galvanometer" and are not of two types—moving coil and cathode ray. The moving iron oscillograph deserves mention, the moving coil oscillograph is not sensitive (as a member of the authors' class of galvanometer must be) and the cathode ray oscillograph would still be a laboratory toy were it only a galvanometer.

The power engineer will probably find the book more valuable than these critical comments suggest. A good book, first edition, would be a very good book, second edition, if attention be given to the points mentioned.

Tables of Physical and Chemical Constants and some Mathematical Functions

By Dr. G. W. C. Kaye and Prof. T. H. Laby. Eighth edition. Pp. vii + 162. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1936.) 14*s*. net.

IT is difficult to imagine a modern physical laboratory which does not possess its well-thumbed copy of "Kaye and Laby"; and it is a special pleasure to see that our old friend, clad in gayer harness than has been his wont, has now reached his eighth edition.

Kaye and Laby's Tables is a work the utility of which is quite out of proportion to its modest dimensions. In a small and handy volume of tables, the editors have to pick and choose, and they have two main duties to perform: to see to it that they let down the users of the tables as infrequently as possible, and to arrange their matter so that the searcher for a number may find it with ease. How well the editors have accomplished their task is obvious—an eighth edition speaks for itself.

This edition preserves all the old features, and a number of recent data have been added. If a very mild criticism may be ventured, it is that the editors, in their anxiety to introduce new data under the appropriate heading, have had to cut short the amount of new information which they could have given us. In all instances of physical properties which vary with pressure and temperature, it is advisable to list these properties over as wide a range as possible—preferably by means of equations, when dealing, say, with homologous organic compounds. For heavy water, some preliminary investigations have been made, and density, viscosity and surface tension, for example, have been investigated at different temperatures. Exigencies of space have made it impossible for the editors to do more than quote one or two figures—it were impossible otherwise to squeeze them in under their appropriate heads. It is much to be hoped that the editors will, in the ninth edition which is surely contemplated, give the latest information which may be needed in any detail by way of a separate sheet or two at the end of the book. A detailed index, which already exists, would serve as guide, and much more additional information would be easily made accessible to the reader.

The new edition may be heartily commended, both to users of the old editions, and to those unfortunates who know not how Kaye and Laby's Tables *delectant domi, non impediunt foris.* A. F.

Light

By A. E. E. McKenzie. Pp. x+178+10 plates. (Cambridge: At the University Press, 1936.) 2*s*. 6*d*.

THIS unassuming little volume presents the elementary facts of optics to pupils of School Certificate standard in most attractive fashion. The author has evidently written the book *con amore*, and his enthusiasm for his subject should be infectious.

He has accepted the recommendations in the report of the Physical Society on "The Teaching of Geometrical Optics" with respect to sign convention, and of the conventions recommended has adopted that in which distances actually travelled by a ray of light are taken as positive, and distances measured along a virtual ray as negative.

The subject is developed in its usual order, and the book is illustrated by an excellent series of photographs, including a most remarkable photograph of a desert mirage as seen in Persia. An ample number of numerical examples are appended to the chapters.

The book can be unreservedly commended.

A. F.

Philosophy and Psychology

The Way to Happiness for Humanity:
a Modern Philosophy for Everyone. By "Amator". Pp. 324. (London: The Good Hope Publishing House, n.d.) 4*s*. net.

IF it is true that anyone who thinks is a philosopher, it is equally true that anyone who has thoughts to put forward after careful consideration is entitled to do so, provided he satisfies himself of their appropriateness as to form and content. Moreover, if it is true that happiness is the goal of any mortal man, we are all of us entitled, whatever our particular interests, to think of the best means of attaining happiness; and when we consider that our way may be of some use to others, then it is almost our duty to communicate to the world at large the results of our thought. It is probably such and similar thoughts that prompted the anonymous author of this work to write it. In expressing his opinion he shows great courage and a thorough understanding of the issues involved. As an attempt to solve one of the major problems of philosophy, "The Way to Happiness" deserves praise and careful consideration.

Personality Maladjustments and Mental Hygiene:
a Textbook for Psychologists, Educators, Counselors and Mental-Hygiene Workers. By Dr. J. E. Wallace Wallin. (McGraw-Hill Publications in Psychology.) Pp. xii+511. (New York and London: McGraw-Hill Book Co., Inc., 1935.) 18*s*.

MENTAL hygiene has become so much a matter of everyday politics that well-balanced books on the subject are welcome. This is a sane and readable account of personality difficulties and how to deal with them. How we wish the dictators and other psychopaths in the world could apply mental hygiene principles to themselves and their henchmen. The author very wisely says: "A large proportion of our social and political distempers can, doubtless, be traced to the disfigured, discordant, dissatisfied personalities that inhabit the earth. . . . Mental health and mental hygiene in international as in personal relations means facing facts and issues candidly and dispassionately, without bias, duplicity, hypocritical diplomacy and subservience to insensate emotional urges."

Twentieth Century Psychiatry:
its Contribution to Man's Knowledge of Himself. By Dr. William A. White. (Thomas W. Salmon Memorial Lectures.) Pp. 198. (London: Chapman and Hall, Ltd., 1936.) 10*s*. 6*d*. net.

THIS series of lectures presented by Dr. White to the New York Academy of Medicine in 1935 makes most interesting reading both to the psychiatrist and to the layman. Psychiatry is an ugly word but has a wide meaning, and it is a pity that the average layman has little idea of its meaning. To-day it covers not only the work of the old-time alienist but also that of the modern workers in mental hygiene, criminology, sociology and wide ramifications in sundry ancillary subjects.

We commend these lectures to those who are sympathetic to what is one of the most technical, most difficult and most exhausting branches of modern specialized medicine.

Technology

Practical Photo-Micrography

By J. E. Barnard and Frank V. Welch. Third edition. Pp. xii+352+23 plates. (London: Edward Arnold and Co., 1936.) 21*s*. net.

THE appearance of the third edition of "Barnard and Welch" is a very welcome event. Broadly speaking, it follows the plan of its predecessors, except for a number of recent developments which add materially to its value. These are concerned with the application of infra-red radiation to microscopy, and an extended technique suitable for opaque objects. In this latter connexion one would have been glad to see some specific reference to recent work on the photomicrography of polished minerals and ores by polarized light, such as has achieved considerable success both at Cambridge and on the Continent. In metallurgical practice, the tendency to forget that magnification exerts little influence upon exposure times (due to the self-condensing action of the objective) is specially mentioned—a most valuable reminder. Again, the photo-micrography of mercury droplets as a method of perfect centration is a very elegant device, beautifully illustrated for both ordinary and dark-ground illumination. As the authors remark, skill and long experience are more important than complex equipment. That is the conclusion which many workers in this field have reached, encouraged maybe by the guidance of "Practical Photo-Micrography".

F. I. G. R.

The Gramophone Record

By H. Courtney Bryson. Pp. xix + 286. (London: Ernest Benn, Ltd., 1935.) 21*s.* net.

THE gramophone record industry is so specialized, particularly in the manufacture of disk records, that although the industry is half a century old and substantial developments have taken place in the last decade, there have been hitherto no books or 'inside' information published which give a comprehensive account of the extremely delicate processes involved in making multiplications of a master record perhaps a million times. The author gives an amusing, but intelligent, historical account of the pioneers and their early efforts in recording natural sounds, and then carefully states the nature of the problem and how it is solved at the present time.

The text is profusely illustrated with photographs of technical operations, so that the reader is not left in the air with theoretical notions. The author is a specialist in plastics, and hence the valuable part of the book is concerned with the materials, which are necessarily the limiting factors in making records of technical excellence, their properties and technique of handling. The final chapter deals with possibilities of departing from the prevalent black shiny disk, but the author is not hopeful. We are also pessimistic, since the shellac disk is the cheapest method of obtaining an artistic record which is tolerable, and on account of the rapid decline in the sales of records, the large record firms, which have substantial monopolies, will be loath to change to an improved system. These aspects tend to make the present text the more valuable. L. E. C. H.

Stereoscopic Photography:

its Application to Science, Industry and Education. By Arthur W. Judge. Second edition, revised and enlarged. Pp. xi + 340 + 22 plates. (London: Chapman and Hall, Ltd., 1935.) 21*s.* net.

IN Great Britain the amateur photographer, unlike his colleague on the Continent, is not as a rule interested in stereoscopic photography: its developments therefore have been mainly scientific and industrial. The additional matter contained in this new edition of Mr. Judge's book reflects this condition. The most important advances perhaps are in connexion with medical work, ophthalmic appliances and the recording of X-ray 'screening' experiments under improved conditions. Nevertheless, the classical part of the subject permits of wide extension, such as the application of geometrical optics to the more refined problems of binocular vision. The book is thoroughly practical and provided with an abundance of illustrations.

In the past, it has been difficult to obtain up-to-date information of the kind in English: this volume therefore should appeal to a wide circle of inquirers. F. I. G. R.

Forthcoming Books of Science

Agriculture and Horticulture

Jonathan Cape, Ltd. Fool's Garden—Muriel Stuart.

English Universities Press, Ltd. The Vegetable Book—W. E. Shewell-Cooper.

PRINTED IN GREAT BRITAIN BY FISHER, KNIGHT AND CO., LTD., ST. ALBANS

on such a section of a crystal as a crystal face. Hence all observations of small-scale regular markings such as etch figures and slip bands at the crystal surface and especially their minimum dimensions are highly relevant to the subject.

The dimensions of the sharply defined triangular markings shown in numerous photomicrographs[3] of natural (111) faces of diamond are all large compared with the hypothetical dimensions, about 1 μ, of mosaic irregularities. Whilst examining the surface irregularities on some unusually good specimens kindly lent by Prof. W. T. Gordon for X-ray study, it was noticed that a number of regions on one specimen which at ordinary powers of magnification appeared to be free from triangular markings, at magnifications of about 750 diameters showed many minute triangles (Fig. 1). Their orientation was normal, with the angles pointing towards octahedron edges, and the edge of the smallest clearly resolved triangle measured 1·3 μ.

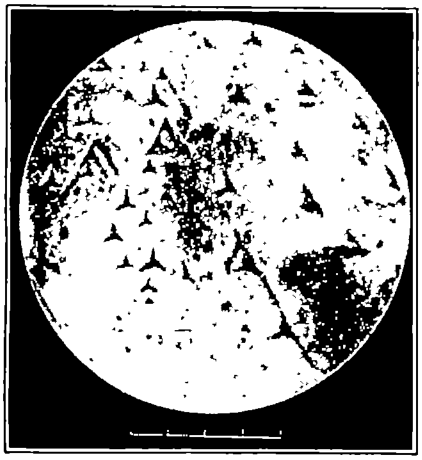

FIG 1. Photomicrograph of (111) face of a diamond showing some triangular markings of 'mosaic' dimensions. Each scale division represents 0 01 mm.

These abnormally small regular markings were found only in groups and only at the edges of the crystal face. They were not detected on any of the other specimens examined similarly. The specimen measuring about 6 mm. × 4 mm. was the only one from the new diamond field at Sierra Leone. No trace of striations of this 'mosaic' order of magnitude was detected optically, but even the triangular markings themselves were difficult to observe because of their minuteness and the high transparency of the diamond. The optical difficulties were too great to justify an attempt to find the unit size of the largest equilateral triangular network fitting *all* the observed triangles[4]. For the (111) face of bismuth this derived quantity, claimed to be of the order 1·4 μ, is about the same as the observed dimensions of the edge of the smallest triangle on the diamond. Sufficient contrast to see or to photograph the markings was got by defocusing, and I am indebted to Mr. G. A. de Belin for the trouble taken to get the photomicrograph reproduced.

W. H. GEORGE.

Physics Laboratory,

Optical Experiments on Liquid Helium II

THE anomaly in the specific heat of liquid helium at 2·19° K. has the same shape as that of the λ-point anomaly in crystalline substances. In crystalline bodies the λ-point anomaly, similar to that shown by ferromagnetic bodies at the Curie point, is due to some process connected with a change of order in the crystal.

It is natural to suppose that in the case of liquid helium II we also have to do with some form of order. As this type of transition is observed in liquids when liquid crystals are formed, it is not impossible that liquid helium at temperatures below 2·19° K. also forms liquid crystals.

Liquid crystals are anisotropic, and it is therefore interesting to study the optical properties of liquid helium II. If liquid helium II does in fact form liquid crystals, polarized light, on passing through a layer of helium, must be depolarized, as on its way it traverses a large number of optically anisotropic regions of different orientation.

In our experiments a layer of helium, 10 cm. in length, was placed between crossed nicols. The accuracy was such that a change in the intensity of light corresponding to a rotation of the prisms of ± 1·5° could easily be registered. On cooling the helium from 4·22° to 1·72° K. no change in the intensity of the light could be detected. It is possible that the effect could not be observed owing to the small dimensions of the liquid crystals. We therefore studied the Kerr effect in liquid helium II at 1·72° K. in a constant field of 63,000 volts per cm. No change in the light intensity could be observed with crossed nicols, the planes of polarization of which formed an angle of 45° with the direction of the electric field.

Assuming that the field was sufficiently strong completely to orient the optical axes of the crystals, we have computed that the anisotropy of the refractive index for helium II is less than 7×10^{-8}. If the optical axes were oriented perpendicularly to the direction of the field, this ratio would be 1×10^{-7}.

As the optical anisotropy which might have been expected in helium II lies within the accuracy of measurement, it must be assumed that the anomaly in liquid helium cannot be explained by a transition into the liquid crystal state.

Infra-red Absorption Spectrum of Heavy Phosphine (PD_3)

THE infra-red absorption spectrum of PD_3 has been investigated with the view of testing the applicability of the 'valence force field' in correlating the fundamental vibration frequencies of a pyramidal molecule of the type YX_3. If it is assumed that the valence force field applies to PH_3, then one can deduce the values of the force constants of this molecule from its known vibration frequencies. This has been done by Howard[1], who gives $3 \cdot 09 \times 10^5$ dynes/cm. for the force required to alter the PH distance, and $0 \cdot 34 \times 10^5$ dynes/cm. for that required to alter the HPH angle. From these data one may compute the frequencies of the PD_3 molecule (since it is permissible to assume that these force constants are not appreciably altered by the substitution of a deuterium for a hydrogen atom). The frequencies of PD_3 are thus predicted as $\nu_1 = 1{,}630$ cm.$^{-1}$, $\nu_2 = 1{,}639$ cm.$^{-1}$, $\nu_3 = 775$ cm.$^{-1}$, and $\nu_4 = 871$ cm.$^{-1}$, all of which should be observable in the infra-red.

Strong absorption bands have been observed in gaseous PD_3 at approximately 1,670 cm.$^{-1}$, 790 cm.$^{-1}$ and 730 cm.$^{-1}$. These may reasonably be identified as ν_1, ν_4 and ν_3 respectively. The frequency ν_2 which is not observed in PH_3 is also apparently too weak to be observed in PD_3. Weaker bands have also been observed at 2,325 cm.$^{-1}$ and 3,280 cm.$^{-1}$ which may readily be interpreted as the combination bands $\nu_1 + \nu_3$ and $2\nu_1$ respectively. Three Raman lines have been observed for liquid PD_3 by Hemptinne and Delfosse[2] at 1,664 cm.$^{-1}$, 805 cm.$^{-1}$ and 748 cm.$^{-1}$. These obviously correspond to our three main absorption bands and have, in fact, been given the same interpretation by those authors. The results are tabulated below.

Fundamental Frequencies of PD

	ν_1	ν_2	ν_3	ν_4
Calculated on valence force field	1,630	1,639	775	871
Observed in infra-red (gas)	1,670	—	730	790
Observed in Raman effect (liquid)	1,664	—	748	805

It is immediately obvious that the discrepancy between observed and calculated values is a fairly serious one. It is much larger, for example, than in the corresponding comparison[1] for ND_3. One must conclude that the simple valence force field is a rather incomplete representation of the force field in this type of molecule, and that considerable allowance must be made for interaction and anharmonic terms in the potential function. The determination of those necessitates a very accurate knowledge of the spectrum of PD_3, which is therefore now being investigated under high dispersion.

We are very much indebted to Mr. I. L. Bolland, of the University of Edinburgh, for his kindness in supplying us with the sample of PD_3 used in this investigation.

Atmospheric Oscillations

As is well known, the semidiurnal barometric oscillations indicate that the atmosphere has a free oscillation of a period of 12 hours[1]. On the other hand, G. I. Taylor's evidence[2] from the propagation of waves of explosion points to a free period of 10½ hours. Moreover, the diurnal variation of the earth's magnetic field, when interpreted by the 'dynamo' theory, shows[3] that at the upper conducting layer the pressure oscillations are nearly 180° out of phase with the observed pressure oscillations at the ground. Also, the required conductivity of the layer is larger than the value that can be inferred from radio soundings.

It appears that all the above mentioned facts can be reconciled if we assume a temperature distribution in the atmosphere such as is shown by the curve T in the accompanying figure (Fig. 1). The rise of temperature between 37 km. and 60 km. has been inferred by F. J. W. Whipple[4] from the abnormal propagation of waves from gun-fire, and is in general agreement with the results of similar experiments carried out in Germany. This atmosphere has one mode of free oscillation (1), with a period of about 10½ hours and a corresponding velocity of long waves agreeing exactly with the velocity of the Krakatau wave. It also has another mode of free oscillation (2), with a period very nearly 12 hours. The ratio of the horizontal velocities at any level to the value at the ground is shown by the curves $U^{(1)}$ and $U^{(2)}$. The pressure oscillations are proportional to U. It is seen that, while $U^{(1)}$ is of the same sign throughout, $U^{(2)}$ vanishes at about 30 km., and is of opposite sign at higher levels. The atmospheres above and below this level swing mainly horizontally in opposite directions, and there is a high pressure in one part whenever there is a low pressure in the other. The velocities at the level of 100 km. are, especially in (2), about 100 times greater than at the ground, so that a correspondingly smaller conductivity is required for the conducting layer of the dynamo theory. It will be noticed, however, that the energy densities, which are proportional to the density and the square of the velocities, ultimately vanish exponentially with height, as is shown by the curves $E^{(1)}$ and $E^{(2)}$. From the run of these curves one might expect that a disturbance like the Krakatau eruption which was concentrated at the ground would excite mode (1) and would therefore be propagated with a corresponding speed. That the Krakatau wave was shallow can be inferred from the fact that the wave front was considerably modified by the trade winds, as was shown by Taylor.

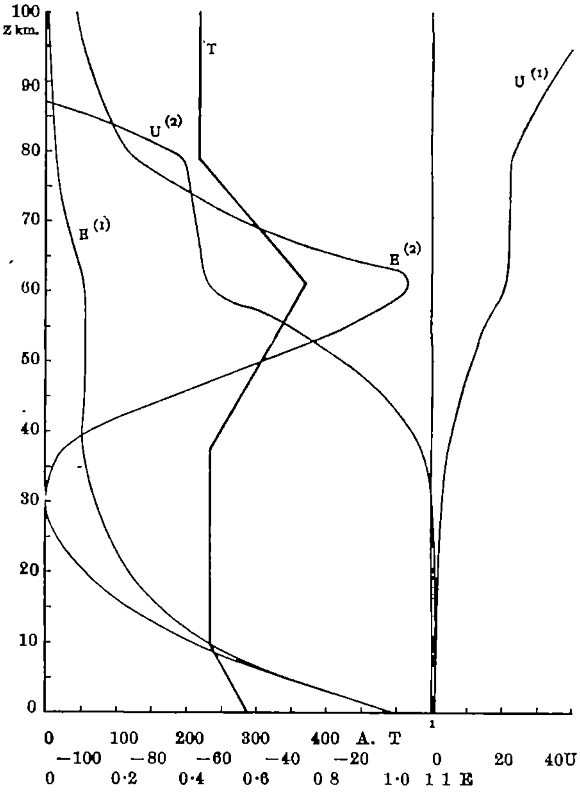

FIG. 1. Assumed vertical distribution of temperature T and computed velocity U and energy density E for the two modes of free oscillation (1) and (2).

Although the motion is mainly horizontal, the large amplitudes of the oscillation at high altitudes are accompanied by considerable vertical displacements of the atmospheric layers. These are of the order of a km. at the 100 km. level, but increase exponentially with height until they begin eventually to be damped by the increasing kinematic viscosity and thermal conduction. It is thus possible that the anomalous variation of height and ionization of the F_2 layer, as reported by Appleton and Naismith[5] and Martin and Pulley[6], might be associated with the semidiurnal oscillation of the atmosphere. Were it not for the retardation by viscosity and conduction, the upper layers would be expected to reach their maximum height at about 9.30 a.m. and 9.30 p.m.

A detailed report of this investigation will appear elsewhere.

Fossil Human Remains from Kanam and Kanjera, Kenya Colony

IN NATURE of March 9, 1935 a letter appeared from Prof. P. G. H. Boswell upon this subject, and I should like to comment upon certain issues raised. Prof. Boswell wrote: "Unfortunately, it has not proved possible to find the exact site of either discovery, since the earlier expedition (of 1931–32) neither marked the localities on the ground nor recorded the sites on a map". This sentence gives the impression that no adequate measures were taken to record the position of the discoveries. Actually, steps were taken which would have proved adequate had not all the photographs, taken especially for the purpose, failed owing to an unsuspected hole in the bellows of the camera. I did not record the sites on a map because there was no map of sufficient accuracy available, and I had not the means of making one at that time. I might have tried to obtain the services of a surveyor, but that would have been costly and I was saving all the money I could for a second visit to Oldoway, which I, at the time, believed was more important.

When we went to Kanam and Kanjera, we had only recently returned from Oldoway, where the geologists had decided that the evidence for the great age of the Oldoway skull was geologically sound. I had accepted their verdict[1] (which was proved to be wrong after my return to England[2]) and I had consequently withdrawn my earlier attack[3]. When I was at Kanam the evidence of Oldoway was once more being questioned[4], and so I was arranging to revisit Oldoway with Mr. Wayland, the director of the Geological Survey of Uganda, in order to re-examine the evidence.

Later events have proved that this was an error of judgment, and that it would have been better to get a surveyor for Kanam and abandon the idea of revisiting Oldoway, but it is easy to be wise after the event. I believed at the time that the sites were adequately marked.

In spite of everything, I maintain that I showed Prof. Boswell the actual stratum from which the Kanam mandible was obtained, as well as the position within circumscribed limits. At Kanjera I showed him the exact spot where the residual mound of deposits had stood which yielded the Kanjera No. 3 skull *in situ*. We ourselves dug away most of the mound in 1932, and the small remaining portion had been eroded away. But the fact that I did show Prof. Boswell the site is proved by a small fragment of bone picked up there in 1935 which fits one of the 1932 pieces.

Another issue raised by Prof. Boswell is connected with the accidental use of a wrong photograph. He wrote: "Moreover, the photograph of the site where the mandible was found, exhibited with the jaw fragment at the Royal College of Surgeons, was, through some error, that of a different locality; and the deposits (said to be clays) are in fact of entirely different rock (volcanic agglomerate)." This sentence is even more misleading than the previous one, and there are two points which I must discuss.

First of all, the accidental use of a wrong photograph. As already mentioned, my own photographs of the site all failed, and I consequently had to make use of photographs taken by other members of the expedition. In view of this, I carefully refrained from using any photographs *as evidence* in connexion with my claim for the antiquity of the Kanam mandible, and only used them to show the general nature of the sites. I had among others a photograph taken by Miss Kendrick and marked on the back "Kanam West, site of Deinotherium tooth". Owing to a mistake on my part, which I freely admit and deeply regret, this was taken to be a picture of the site where the deinotherium tooth was found which led to the discovery of the human mandible fragment. I therefore used it in good faith to give a general view of the site. In 1935, we found that this picture was of a different part of the Kanam West exposures (about 400 yards away) where the first deinotherium tooth found in the area came from.

The sentence quoted above ends "and the deposits (said to be clays) are in fact of entirely different rock (volcanic agglomerate)". From articles in the Press (see *Discovery*, April 1935, etc.) and from conversations I have had, it is clear that this sentence has been very widely interpreted both in England, on the Continent and in the United States, as meaning in effect "Boswell says Leakey does not know the difference between a clay and a volcanic agglomerate!" I understand from Prof. Boswell that he did not mean this at all, and that the words were only meant to mean that the deposits visible in the wrong picture are agglomerates whereas the deposits at the site itself are (as I said) clays.

There are several other issues that I would like to discuss, including the meaning of the word 'horizon' in connexion with the Kanjera finds. I used the word in the sense defined by several geological text-books, but it seems to have a different meaning for Prof. Boswell. I will not, however, trespass further on space of NATURE, as I hope to have an opportunity before long to discuss the matter further.

Colorimetric Estimation of Phosphorus

To determine the rate of colour formation and the optimum time for taking readings in the Fiske and Subbarow method of estimating phosphorus microchemically, we have used a simple type of photoelectric colorimeter (to be described in detail elsewhere) which allows the chemical reaction to be followed continuously until a state of equilibrium is reached. The method has been developed for the purpose of obtaining more accurate figures for the phosphorus content of the whole blood and its separate fractions (plasma, serum and red cells) than those hitherto obtained by other (visual) methods.

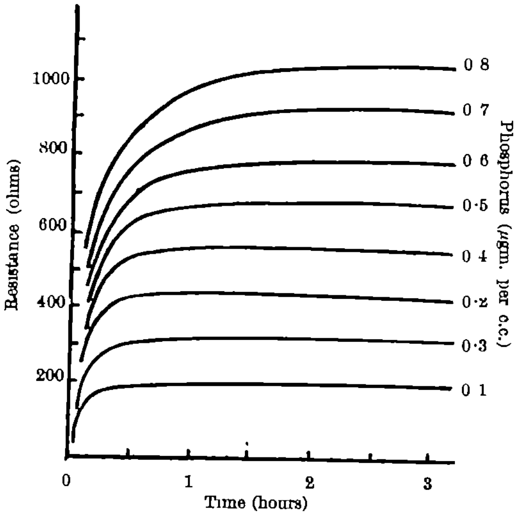

FIG. 1. Relation of colour intensity to time. Curves for the smallest amounts of phosphorus measured have been omitted; in the interests of clearness, the steep ascents in the earlier stages of colour formation have also been omitted.

Our apparatus enables us to detect 10^{-8} gm. of phosphorus per c.c. of solution, and to measure accurately changes of less than 10^{-7} gm. The reagent used, which differs slightly from that given by Fiske and Subbarow, consists of 0·1 gm. of 1 : 2 : 4 aminonaphthol-sulphonic acid, 5·48 gm. of sodium metabisulphite, 1·2 gm. of crystalline sodium sulphite dissolved in distilled water to make 50 c.c. of the solution. When the component substances are in these proportions, the acid remains in solution unless the temperature changes markedly. A beam of approximately monochromatic light which, passing through a liquid filter containing the solution to be examined, falls on to a photo-electric cell and so gives rise to a photo-electric current, is balanced against a current generated by a beam from the same source, which has, however, passed through a glass vessel containing only distilled water. After the addition of 2 c.c. of an ammonium molybdate and sulphuric acid solution and then of 1 c.c. of the modified Fiske and Subbarow reagent to the test solution, the characteristic blue colour that forms may be followed by means of a variable resistance which is manipulated so that the spot of light of a mirror galvanometer (of low resistance) remains undeflected.

By measuring solutions containing known amounts of phosphorus (from 0·03 to 1 microgram per c.c.) we calibrated the instrument to express intensity of colour in terms of the balancing resistance; it was found that, roughly, a difference of 0·05 microgram of phosphorus per c.c. produced a colour which caused a change of resistance of 50 ohms, a difference of 1 ohm producing an easily perceptible deflection even with an ordinary laboratory galvanometer. The calibration curve is very nearly linear. When the intensity of colour, expressed in ohms, is plotted against time, curves of the type shown in Fig. 1 are obtained.

These curves show that the colour begins to form immediately after the reagents have been added and increases rapidly in intensity until a comparatively steady state is reached: actually, the colour continues to deepen for many hours. When the quantity of phosphorus present is very small, this approximately steady value is attained in about 20 minutes, but when the amounts are of the order of 0·5 μ gm. per c.c., the colour should not be read until two hours have elapsed since the reagents were added. The curves shown in Fig. 1 are drawn from readings taken at intervals of 2½ minutes in the early stages, then 5 minutes, later 15 minutes and hourly. It also follows from these curves that, when the colours are read in the ordinary ocular colorimeters, the varying rates of development of colour in the standard and the unknown will escape notice owing to the relative insensitiveness of the method.

A merit of the present apparatus is that once the calibration curve for standard amounts of phosphorus has been determined, it is no longer necessary to prepare a standard for comparison with the unknown solution, since the liquid filter used to obtain an electrical balance need contain only distilled water. The advantage of being able to measure accurately the successive changes of colour in the solution is obvious.

The same method is now being applied to other standard colorimetric tests, and it appears probable that the interval of time within which the respective colours are to be read will be found, as in the present case, to be greater than that usually allowed, since more accurate results will be obtained when the measurements are made on the nearly horizontal branches of the resistance curves. In some tests, such as that for cholesterol, it will be possible to determine the optimum time for reading the colour before it begins to fade.

Under the auspices of the Cancer Research Committee of the University of Sydney, we are using the above method to measure the amounts of certain constituent substances in pathological human blood.

Surface Properties of Non-Aqueous Solutions

A CLOSE study of the surface properties of capillary-active solutions of compounds forming homologous series has shown that the surface activity increases regularly with the molecular weight (Traube's rule). Only aqueous solutions have, however, been thoroughly investigated, and little is known of non-aqueous systems. Since organic solvents have much lower surface tensions than water, the changes produced by solutes will doubtless be much smaller, but the following results show that in certain solvents interesting effects of a similar nature can be observed.

I have determined the surface tension of solutions of different normal alcohols in aniline by means of a Traube stalagmometer. Aniline was chosen as solvent because of its comparatively high surface tension ($\varsigma_{20^\circ} = 42{\cdot}9$ dynes/cm.). Although the lowering of the surface tension ($\Delta\varsigma$) is much smaller than in aqueous solutions, it was clearly established that, as in water, $\Delta\varsigma$ is the greater the higher the concentration (c) of the alcohol and that for isomolecular solutions of different alcohols $\Delta\varsigma$ is the greater the higher the molecular weight. The surface tension-concentration curves were of the same type as generally encountered in aqueous solutions, that is, ς falls most rapidly at small concentrations. For dilute solutions (c less than 0·1 mol./lit.) $\Delta\varsigma/c = F$ can be regarded as constant and the following table gives the F-values for the different alcohols :

Alcohol	F
Ethyl	(1 6)
Propyl	3·4
Butyl	6·5
Amyl	9 6
Hexyl	12 8
Octyl	18 8
Decyl	25 2
Dodecyl	31 0

While in aqueous solutions F progresses geometrically as we ascend the homologous series, we find here a regularity of a less pronounced character, namely, from propylalcohol onwards the F-values form an arithmetical progression as do the molecular weights. Thus while in aqueous solutions F_{n+1}/F_n is a constant (generally 3), we find here $F_{n+1} - F_n =$ constant $= 3$.

The fact that F_{n+1}/F_n approaches the value 1 as we move up the series indicates that the influence of the additional CH_2-group upon the surface energy becomes the smaller as the hydrocarbon-chain becomes longer.

It remains to be seen whether in other cases where the solutes have much smaller surface tensions than the solvent similar relationships will be found.

Rate of Absorption of Oxygen by Sodium Sulphite Solution

DURING the course of some measurements on the rate of absorption of gaseous oxygen by aqueous sodium sulphite solution, it was found that, under certain conditions, stirring the liquid beneath the surface without in any way agitating the latter *decreased* the rate of absorption below that of the unstirred liquid.

The apparatus used consisted essentially of a glass tube into the bottom of which a glass rod was sealed to act as a pivot for a glass stirrer below the liquid surface. This stirrer was hollow and contained iron wire so that it could be moved, by means of a magnetic field rotated externally, without breaking the liquid surface at any point. The other end of the tube was connected to a manometer. This portion was constructed in triplicate to ensure adequate control, and provision was made whereby the whole apparatus could be exhausted and the gas to be used admitted as required, each tube then being connected separately to its particular manometer.

Two tubes of approximately normal sodium sulphite solution were compared; each of these contained similar stirrers but only one of them was stirred (care being taken not to agitate the liquid-gas surface). After the initial rapid absorption, when the rate had become constant and after applying corrections, it was found that the rate of gas absorption by the solution the bulk of which was stirred was in general 48 per cent *less* than the rate at which the gas was absorbed by the unstirred liquid.

A systematic study of this phenomenon is being undertaken, and it is hoped to publish some of the results of the investigation shortly.

Enolization of Oxycholesterilene

$\Delta_{5\,6}$-UNSATURATED sterols may be converted to the 7-dehydro compounds by the method of Windaus, Lettré and Schenck[1]. An alternative route, which is being examined in these laboratories, lies in the enolization of 7-ketocholesterol (I).

Acetylation of (I) resulted in the removal of the C_3-hydroxyl, oxycholesterilene and the acetate of oxycholesterilene being obtained. The latter compound (II) had m.p. 90°–92°, $[\alpha]_D$ $-222°$, $[\alpha]_{5461}$ $-283°$ (found: C, 82·0; H, 10·9. Calc. for $C_{29}H_{44}O_2$: C, 82·1; H, 10·4 per cent). Unless a shifting of the double bonds has taken place, this compound (II) will have the structure shown in Fig. 1. Its ultra-violet absorption spectrum has been examined by Dr. R. K. Callow, who reports that it is consistent with this formula. In view of the mobility of the ergosterol ring system, however, the product m.p. 90°–92° may be contaminated with an isomeride.

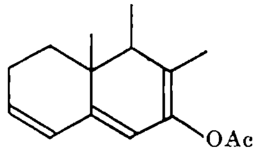

FIG. 1.

This point is at present under investigation. Methods for the preparation of $\Delta_{5\,6:7\,8}$-cholestadiene-3 : 7-diolacetate are being examined and the results will shortly be published elsewhere.

Bilateral Gynandromorphism in Feathers

LILLIE and Juhn[1] suggested that the reactivity to œstrone sometimes manifested only on one side of a feather depends upon a low growth-rate of the tissue at the time, which rate they considered may be different on the two sides. These original views were immediately criticized by other workers[2,3]. They seem to have been greatly modified in exhaustive papers by Fraps and Juhn[4]; but it does not appear that the senior author has abandoned them.

Greenwood and Blyth[5] have shown that asymmetrically coloured feathers may be produced in the Brown Leghorn capon by the intra-dermal injection of small doses of œstrone. I have sectioned the bases of six asymmetrically marked feathers obtained in this way in which the rachis was substantially straight and the barbs on each side of a similar length. I have counted in a section the barbs cut on each side and compared the lengths of the two halves of the collar. The side of the feather which had reacted most to œstrone corresponded with the larger side of the germ and had therefore on the concrescence theory presumably grown more slowly (as required by the theory of Lillie and Juhn) in two cases. The opposite was true in three cases. There was no discernible difference in one case. The differences were small—perhaps trivial. Five of them lay between two and seven per cent of the total number of barbs cut in the section used. One specimen, however, showed nineteen per cent excess of barbs on the non-reacting side—the opposite of what Lillie and Juhn would seem to require. The differences in length between the two sides followed closely the differences in number of barbs. In each case the œstrone mark was on the side of the feather directed towards the site of injection.

These results do not appear to afford support to the theories of Lillie and Juhn, but seem to agree rather with the results of Greenwood and Blyth. It is hoped shortly to publish a fuller account elsewhere of this and similar work from this Department.

Origin of the Word 'Solute'

IN view of the recent discussion as to the first use of the word 'solute'[1], it may perhaps be of interest to notice that the word is used in 1732 in the modern sense by Boerhaave[2], in the Latin form *solutum*. In discussing the action of solvents, he states that the effect is the division of the dissolved substance into particles which are thoroughly mixed with the particles of solvent: "ut particulae solventis inter partes divisas soluti", which Shaw[3] translates: "so that the particles of the solvent remain thoroughly intermixed among those of the solvend". The name is used by Boerhaave throughout his long discussion of solutions, although he sometimes speaks of *partes solvendi* as an alternative. Whether the name is used before Boerhaave I cannot say.

Points from Foregoing Letters

SIR C. V. RAMAN and N. S. Nagendra Nath give a brief outline of the several stages by which the theory dealing with the diffraction of light by high-frequency sound waves was developed, and state that its latest extension explains several additional facts, including the reason why supersonic waves can be seen directly through a microscope focused on a plane to the rear of a sound-wave cell.

A photomicrograph of a (111) face of diamond showing triangular markings of the size predicted by the 'mosaic' hypothesis of crystal structure is submitted by Dr. W. H. George. According to that hypothesis, even in a perfect crystal the uniform lattice structure is interrupted over narrow regions distributed periodically throughout the crystal.

Experiments with liquid helium by L. W. Shubnikov and A. K. Kikoin show that it does not form liquid crystals at 2·19° K. The anomaly in the specific heat of liquid helium observed at that temperature cannot therefore be ascribed to a transition to the liquid crystalline state.

The infra-red spectrum of heavy phosphine (PD_3) has been investigated by Dr. G. B. B. M. Sutherland and G. K. T. Conn. Their results (which agree quite well with those on the Raman spectrum of the molecule), do not agree so well with the frequencies predicted from the spectrum of ordinary phosphine (PH_3), thus indicating that a simple valence force field is not very satisfactory for correlating the vibration frequencies of a molecule of this type.

C. L. Pekeris points out that when the increase of temperature in the atmosphere between the levels of 30 km. and 50 km. is taken into account, the atmosphere is found to possess two modes of free oscillations of periods of 10½ hours and 12 hours respectively. In the 12-hourly oscillation there is a nodal surface at about 30 km., the atmospheres below and above it swinging in opposite directions. Various observed facts from the oscillations of the barometer, the propagation of waves of explosion and the diurnal variation of the magnetic field are thereby explained. It is also suggested that the anomalous behaviour of the F_2 layer might be associated with the semi-diurnal oscillations of the atmosphere.

Dr. L. S. B. Leakey, commenting upon Prof. Boswell's report on fossil human remains from Kenya, describes the events which led to the inadequate location of the sites.

A method of determining by means of a photo-electric cell the colour changes produced by chemical reagents, enabling the chemical reaction to be followed continuously, is described by Dr. H. L. Brose and E. B. Jones. Graphs are submitted showing the change with time in the intensity of the blue colour produced in the microchemical estimation of phosphorus by the method of Fiske and Subbarow.

The surface tensions of solutions of various alcohols in aniline have been measured by R. Aschaffenburg. As in aqueous solutions, the surface activity increases regularly with the molecular weight, but the regularity was found to be different from Traube's rule.

Stirring the interior of a solution of sodium sulphite (without disturbing the surface) *decreases* the rate at which it absorbs oxygen by 48 per cent, according to W. S. E. Hickson.

Dr. V. A. Petrow states that acetylation of 7-ketocholesterol leads to the removal of the C_3-hydroxyl and the formation of the acetate of 7-hydroxycholestatriene.

P. G. 'Espinasse reports that in six regenerating feathers examined there was no clear relation between the lengths of the two halves of the collar and the reactivity to œstrone of the two sides of the feather produced by them. As the feathers were substantially straight, it appears unlikely therefore that growth-rate determines this reactivity.

Eskimo Cultural Origins in East Greenland

AFTER taking part in Helge Larsen's archæological investigations in Dødemandsbogten on Clavering Island, P. V. Glob excavated twenty-seven houses and a number of graves in Eskimo settlements in Kempe Fjord and King Oscar Fjord (*Meddelelser om Grønland*, 102, 2). These settlements had long been deserted when the fjords were first navigated and mapped by the Swedish expedition under A. G. Nathorst in 1899. Their culture in fact falls entirely within the eighteenth century. The finds from north-east Greenland have been classified into (1) an early culture, coming from the south, comprising Ingsuk types; and (2) a mixed culture in two stages, the early and later north-east Greenland culture, consisting of types from the north, the Thule culture, and local types. The Kempe and King Oscar Fjords settlements do not show evidence of the early culture. The characteristic oval house is absent and no house contains Ingsuk types only. The culture found is the Northeast Greenland in its earlier and later forms, though certain types are new. As found here, it probably originated outside the area, as the result of an admixture of Eskimo with a Thule culture from the north and Eskimo with an Ingsuk culture from the south. The house types fall into two groups, in the earlier of which the house type is large. The small house represents a late stage which was degenerate with diminishing numbers. In the group of large house types there is indication of an additional element from the south, marked by the four-sided house, as well as of the incoming of the later stage of Northeast Greenland from a source not evident, but clearly one in which the Thule types had persisted. A noteworthy feature was the occurrence in a number of houses, in which artefacts were usually numerous, of isolated human jaw-bones. Six in all were found. The reason for their occurrence is not clear, but it may be due to disposal of the dead by partial exposure.

Ethnology of Futuna

IN a report on the information collected during a visit to Futuna and Alofi, islands about 150 miles north of Fiji, in 1932 (Bull. Bernice P. Bishop Museum, No. 138), Mr. Edwin Burrows states that the islanders have been little affected by change. Some of their dances and ceremonies are still performed in the traditional manner, and activities, such as the construction of houses and canoes, agriculture, the preparation of food, and the making of bark-cloth and clothes are unaffected. In such small islands as these, the culture is simpler than in the large Polynesian units, and many features of Samoan and Tongan social organization are absent. For example, there are no talking chiefs and no village maids as in Samoa, nor are there sub-chiefs and a chiefs' language as in Tonga, nor is there the Tongan practice of assigning each individual a fixed position within the kindred. On the other hand, practices now lost elsewhere are here found as essential cultural features—for example, inheritance of the position of master craftsman. Futunan culture, therefore, is not only Western Polynesian, but early Polynesian. Thus, two methods of making bark-cloth are found, felting and pasting. Felting is practised as the only method of making bark-cloth in Hawaii, the Society Islands, the Marquesas, the Cook Islands, the Tuamotus and, in fact, throughout the eastern Polynesian area, with the exception of New Zealand. Pasting is the method of Samoa and Tonga. While both are present in Futuna, there is evidence that pasting is here the more recent. The distribution suggests that felting is the old method, while pasting was invented in Samoa and Tonga and the old method forgotten. The different methods of decorating bark-cloth seem to have a like local origin, freehand drawing being the oldest.

The Argentine Ant in the United States

SOME time previous to 1891 this ant, known as *Iridomyrmex humilis* Mayr, which is an inhabitant of South America, entered the United States at New Orleans. In less than fifty years it has come to invade and establish itself in more than 4,000 square miles of territory, including most of the Southern States and a considerable area of California. An account of this insect, together with methods of its control, has been written by Mr. M. R. Smith (*Circ.* No. 387, U.S. Department of Agriculture, May 1936). It appears that the ant becomes disseminated chiefly via railroad commerce, and is readily transported in consignments of lumber, plants, dry goods, etc. The hold which it has obtained in its adopted territory is due to its ability to produce enormous numbers of individuals able to exterminate competitive species. It thrives both in human habitations and in the open, and can exist up to 4,000 feet. It is chiefly as an indoor pest that it is most troublesome: it is omnivorous and swarms on foodstuffs, etc. Out of doors it affects poultry-keeping and often kills young chicks to obtain their blood: this ant also invades beehives besides fostering aphids and mealy bugs. The official recommendations for its control include systematically planned poisoning by means of a mixture of syrup and sodium arsenite, placed in small containers at specified intervals throughout infested areas.

Northern Harpacticids

KARL LANG has investigated the harpacticids from the Swedish Expedition to Spitsbergen 1898 and Greenland 1899, and although the material was difficult to handle, having been laid aside for more than thirty-five years in alcohol, he has found in it much that is new and interesting ("Die während der Schwedischen Expedition nach Spitzbergen 1898 und nach Grönland 1899 eingesammelten Harpacticiden. *Kungl. Svenska Vetenskapsakademiens Handlingar.* Tredje Serien. 15, No. 4; 1936). There are many new species and these were mostly taken in deep waters (1,750 m. and 2,700 m.) at a greater depth than any harpacticids have been collected before in these regions. The number of species is comparatively large, the number of individuals, in most cases, very small and often confined to a single individual. The present work is purely systematic, the author intending to deal with the geographical distribution in further publications. New species are described of *Cerviniopsis, Bradya, Stenhelia, Ameira, Paramesochra, Argestigens, Eurycledotes, Mesocledotes, Hemicledotes, Parananmopus* and *Rhizothrix*, whilst a new genus and species *Canuellopsis typica* is proposed for a form closely related to *Canuella*. *Eurycledotes echinatus* n.sp., collected at a depth of 1,750 m., possesses a very peculiar alimentary canal, the stomach reaching the third abdominal segment and being strongly lobed before narrowing to a funnel-shaped end with a thick circular muscle. At the sides are large glands, enormously developed. The author suggests that the hind part of the gut may serve for respiration in these great depths. Keys to the species of *Eurycledotes, Mesocletodes* and *Rhizothrix* are given.

A New Group of Filterable Organisms

Sir Patrick Laidlaw and W. J. Elford (*Proc. Roy. Soc.*, B, 120, 292; 1936) have been searching for new organisms in sewage. They removed all visible organisms by filtering the sewage through gradocol membranes with an average pore size between 0·6 μ and 1 μ. The filtrates contained a new group of organisms which may prove to be a link between the larger bacteria and the pathogenic viruses. The larger forms have a diameter of about 0·5 μ, and are visible under dark-ground illumination as small rings. The smallest forms have a diameter of about 0·15 μ. The organisms can be grown in a rich broth. If the small forms are filtered off and cultured, large forms develop, so that the same organism probably varies widely in size at different periods of its life history. The organisms appear to be purely saprophytic, because it was impossible to produce any obvious disease when cultures were administered in various ways to rats, mice and rabbits. Several closely related strains were distinguished immunologically in material from different sources.

Geometrical Laws of Egg Cleavage

It is obvious that the planes of cleavage in the developing egg are conditioned, within limits, by mathematical or rather geometrical laws. Monteil ("L'Oeuf." G. Doin and Cie, Paris, 1936) discusses these geometrical ideas so far as they are applicable to alecithal and telolecithal eggs exhibiting radial and oblique segmentation. The nucleus at the commencement of division tends to take up a position at the centre of gravity of the cytoplasm of the cell and this, while it does not have much effect in the alecithal ovum, is of great importance in the telolecithal ovum. In order to allow for the influence of the yolk in the latter type of egg and not to make the interpretation too complicated, the author deals with the yolk-containing portion of the egg as if it could be divided into zones each with simple proportions of cytoplasm and yolk and the proportions varying from no yolk to no cytoplasm. The axis of the spindle is in general parallel with a tangent to the surface of the egg sphere, and as the cleavage planes are at right angles to this it follows that the internal surfaces of the cells are walls of polyhedrons and not of cubes as is usually depicted in diagrams. Thus, for example, in the eight-celled stage of the frog's egg, the lower internal surfaces of the micromeres together form four sides of a tetrahedron the angles of inclination of which are determinable because they are at right angles to the spindle axes. While the geometrical figures involved in the early stages are simple, they become more and more complex as segmentation proceeds. The provision of short summaries and a large number of diagrams adds considerably to the ease of following the argument.

Pollination of Plums

The effective pollination of orchard crops is an essential factor in the production of satisfactory yields of fruit, and in many cases care must be taken to interplant self-sterile varieties with other sorts to act as pollinators, in which case the flowering periods must overlap. Though the main English plum varieties Czar, Purple Pershore, Victoria and Giant Prune appear to be largely self fertile, cross-pollination is advantageous, and with many other varieties is essential. A recent paper by C. H. Hooper (*J. South Eastern Agric. Coll., Kent*, 38; 1936) contains a classification of plums relative to their degree of self-fruitfulness, and a useful table is given to show varieties in flower at the same time. Pollination is brought about mainly by bees, but observations recorded in the paper cited show that the blossoms are visited by a number of other insects which were counted and identified. The data on flowering periods should prove a useful guide when plum orchards are being planted.

Bactericidal Action of Radiation

The bactericidal action of radiation depends on a number of factors such as the duration and intensity of the exposure, the wave-length, and the nature of the bacterium. A simple and accurate method of studying the effect of these factors has been described by G. Dreyer and M. L. Campbell-Renton (*Proc. Roy. Soc.*, B, 120, 447; 1936). The organisms are spread out evenly on an agar plate. Radiation is then allowed to fall on a localized area about 3 mm. in diameter. A number of such small areas can be treated with different times of exposure or different wave-lengths. The plate is incubated for 22 hours. It is then placed in the 'reading machine', in which a beam of light is thrown obliquely up and the amount of light scattered by the organisms is measured in a gas-filled potassium photo-electric cell. After applying a correction for the dead background, the authors calculate the percentage of survivors from the amount of light scattered in the spot, expressed as a percentage of the amount of light coming from a neighbouring untreated spot. They find that the product of the intensity and duration of irradiation for a given effect is constant over at least an 8-fold range. The shape of the curve connecting percentage growth with log (duration) varies when different organisms are used. The relative bactericidal action of different wave-lengths also varied irregularly and the effect was not proportional to the energy, but in all cases the line 2655 A. was the most effective. The effects of disinfectants were also studied by applying drops of different dilutions to localized areas on agar plates and measuring the effect by the method used in studying the effect of radiation.

Promotion of Nitrogen Fixation in Tropical Soils

At intervals since the beginning of the present century studies have been made of the value of molasses as a soil improver, and a number of investigators have examined the possibility that the action of the molasses was partly an indirect one, that of increasing nitrogen fixation. As there has been a certain conflict of results, particularly on the practical side, there is room for further investigation of the problem, and the contributions of Prof. N. R. Dhar and his co-workers at the University of Allahabad are to be welcomed. They have already shown considerable nitrogen fixation under tropical conditions when energy-rich materials such as soluble carbohydrates or molasses are added to the soil. They are now attacking the general problem of increasing soil nitrogen by supplying the nitrogen-fixing organisms with sources of energy, and in a communication to the Editor dated August 18, 1936, Prof. Dhar and Mr. S. K. Mukerji report appreciable gains in nitrogen content when soils, to which filter paper, dried leaves, or leaf juice had been added, were kept under laboratory conditions for several months. There were still greater increases in nitrogen content when molasses was also added, while soils exposed to sunlight for 6 hours daily gained slightly more than those kept in the dark. Sodium salts of organic acids, namely, sodium citrate, stearate, palmitate and oleate, exposed to light under similar conditions gave smaller but consistent increases in soil nitrogen From one half to two thirds of the added carbon was oxidized at the same time. The authors point out that since molasses and cellulosic materials not only increase the humus content of the soil and improve its physical condition, but also promote nitrogen fixation, the manuring of tropical soils with such substances should be a highly important practical proposition.

Original Laterite of Buchanan

MUCH of the controversy as to the nomenclature of laterites has resulted from the fact that no exact data concerning Buchanan's original laterite have been available. In order to settle the question, Dr. C. S. Fox visited the type localities in Malabar during 1933. His results are now published (*Rec. Geol. Sur. India*, 389–422; 1936). From this paper, it is clear that Buchanan's laterite consists mainly of what would now be called lithomargic laterite and even, in part, lateritic lithomarge. The rocks studied by Buchanan represent but a stage in the passage from granites and gneisses, through kaolin or lithomarge, to a rock consisting mainly of hydrated oxides of alumina and iron in which combined silica is characteristically absent. The latter portion of this process of weathering is now generally known as lateritization, and the finished product is called laterite. Thus Buchanan's 'laterite' is an intermediate form needing some qualifying adjective such as *lithomargic*. Dr. Fox has shown a sense of proportion in recognizing the facts of present usage. Otherwise, had he insisted on a purely academic application of the law of priority, the term laterite would have to be restricted to the lithomargic rocks studied by Buchanan; a completely new term would have to be adopted for the high-level fully formed laterites of the Deccan and elsewhere; and the term lateritization would have to be abandoned. Fortunately, there is no suggestion that any such confusion is likely to be introduced.

Constants of Diatomic Molecules

THE accumulation of spectroscopic data concerning such molecular constants as vibration frequency, ω_e, and internuclear distance, r_e, for diatomic molecules is stimulating further efforts to determine a more accurate relation between these constants. Allen and Longair, Badger and Douglas Clark have each suggested different modifications of the approximate Morse rule, $\omega_e r_e^3 =$ constant. It is found that the results are more satisfactory if attention is paid to the periodic groups to which the atoms forming the molecule belong. Consequently each of the three modifications contains a period constant. Douglas Clark and Howell have also shown that a simple relation exists between the ω_e values of such molecules as A_2, B_2 and AB where A and B belong to the same group. It appears that ω_{AB} is almost equal to the arithmetic mean of the frequencies ω_{A_2} and ω_{B_2}. Dr. N. R. Tawde, of the Royal Institute of Science, Bombay, has sent to NATURE a communication containing the substance of a paper by him, to appear in the *Bombay University Journal*, in which he discusses the same result and also describes his investigation of the variation of the ratio B_e/ω_e for molecules within a given periodic group. As a result of this study, he finds it possible to estimate values of B_e for a number of molecules, and, ultimately, to determine r_e from the relation $B_e = h/8\pi^2 M r_e^2$. Where it is possible to check these calculated values against those already established, agreements to within 2·5 per cent or better are obtained.

Refrigeration in Agriculture

"REFRIGERATION FOR THE FARM AND DAIRY" is the title of an illustrated bulletin by C. A. Cameron Brown, published by the Institute for Research in Agricultural Engineering, Oxford (1*s*. 6*d*.). The preparation of the bulletin was prompted by the number of inquiries on the subject of milk cooling recently received by the Institute, and it is specially intended for the guidance of farmers, small dairymen and in particular the producer-retailer. After an introductory account of the theoretical side of refrigeration, the compression and absorption systems for obtaining the low temperatures are discussed from the practical point of view, the comparative suitability of the various chemicals that can be used, the type of plant employed and its efficiency all coming under review. The second half of the bulletin deals with the application of refrigeration, chiefly in relation to dairying. A full description is given of the two principal methods for cooling milk, namely, the direct-expansion and the circulation methods. The important question of sterilizing is not overlooked, for the choice of cooling plant may be largely determined by the technique in sterilizing preferred. Cold storage is also considered in detail, the equipment required, its mode and operation being fully described, while figures for running costs are quoted from actual farms. Smaller sections are devoted to the question of portable cooling for the dairyman, and refrigeration on the fruit farm, in the bulb and market gardening industry and in poultry farming.

Ammonium Mandelate in Urinary Infections

IN a note in a former issue of NATURE (June 20, 137, 1027), reference was made to this agent in the treatment of *Bacillus coli* infections of the urinary tract, and to a granular form of this compound, 'Neoket', supplied by Boots Pure Drug Co., Ltd., Nottingham. Messrs. Boots now supply an 'elixir' in fluid form, in which the unpleasant taste of ammonium mandelate is successfully covered by the use of suitable flavouring agents, and which is therefore more palatable than 'Neoket'.

International Union of Geodesy and Geophysics

GENERAL ASSEMBLY AT EDINBURGH

THE sixth General Assembly of the International Union for Geodesy and Geophysics was held at Edinburgh during the period September 17–25, under the presidency of Dr. William Bowie (U.S.A.). Of the thirty-two countries that adhere to the Union, twenty-one sent delegates, and in addition thirty guests attended from ten countries (including Germany, Austria, Russia, India, Australia) that are not at present members of the Union. The delegates, guests and those accompanying them numbered in all 378, of whom 261 came from overseas.

At the opening meeting, held on September 17 in the McEwan Hall, the Union was welcomed by the president of the Royal Society, the Lord Provost of Edinburgh, the principal of the University of Edinburgh, and the president of the Royal Society of Edinburgh. The University of Edinburgh conferred its honorary doctorate on the president of the Union, Dr. William Bowie, in the course of the proceedings.

The scientific work of the Union is done by the seven international associations included in it, dealing respectively with geodesy, seismology, meteorology, terrestrial magnetism and electricity, oceanography, vulcanology and hydrology. Each of these held many meetings during the Assembly, some of them commencing their proceedings so early as September 14. Two evening lectures, by Dr. A. L. Day (U.S.A.) on volcanoes, and by Dr. Vening Meinesz (Holland) on gravity measurements in submarines, were given for the public of Edinburgh, and were largely attended.

Social hospitality was accorded to the Union by H.M. Government and the City of Edinburgh, both of which gave evening receptions; the City also gave a garden party. The British National Committee for Geodesy and Geophysics, which organized the meeting, with the aid of Government funds provided through the Royal Society, arranged a Sunday all-day train excursion to the Highlands, and an afternoon party on the closing day of the Assembly. Other afternoon parties were held at the Royal Scottish Museum, where an exhibition of geodetic and geophysical instruments, arranged in connexion with the Union meetings, was opened by Sir William Bragg; and at the Royal Society of Edinburgh, and the Castle. Excursions were also made in connexion with several of the Associations.

The scientific work of the Associations covered too wide and varied a field even to be summarized here. International co-operation is of special importance in the earth sciences, and many useful schemes of international work were initiated or continued. Co-operation between the different Associations is also of importance, and one step taken in this direction at Edinburgh was to set up a special joint commission of the Associations to investigate problems of the earth crust under the oceans.

Among the special papers discussed by the Association of Geodesy were two on pendulum and crystal clocks, by Sampson and Rayner respectively, and one by Bullard on gravity work in East Africa.

The Association of Seismology continued its support of the International Seismological Summary. Among the papers discussed by this Association were one on deep-focus earthquakes, by Gutenberg and Richter, and one on a new type of vertical seismograph, by Somville. On the proposal of Prof. Ishimoto it was recommended that seismic observatories should communicate, for the International Seismological Summary, the direction of the initial displacements in earthquakes.

At the Association of Meteorology about thirty papers were read, and in conjunction with the Association of Oceanography resolutions were adopted urging a more effective collection than heretofore of meteorological data over the oceans; they recommended (1) the creation, with the aid of merchant ships, of an ocean network of upper air soundings, (2) the stationing of a ship near 55° N., 30° W., the region where cyclones most often form, to make meteorological, ærological and oceanographic observations and to collect and re-transmit observations of merchant ships, and (3) an increase in meteorological (particularly upper air) observations in Iceland and the Azores.

Among the decisions made by the Association of Terrestrial Magnetism and Electricity was one to organize temporary observatories to take quick-run records of long-continued magnetic pulsations in Iceland, where they appear to be specially frequent.

Under the auspices of the Hydrology Association many meetings were held, including what appears to have been the first International Commission on Snow, which was largely attended. This Association, like those of Vulcanology, Magnetism, Meteorology and Oceanography, took part in special scientific excursions, in addition to the social excursions arranged for the whole Union.

The administration of the Union will continue to be in the charge of Brigadier H. St. J. Winterbotham as general secretary. The Executive Committee includes the presidents of the Associations, who were as follows: names in brackets indicate new elections for the forthcoming three years: Geodesy, Vening Meinesz, Holland; Seismology, Oddone, Italy (Heck, U.S.A.); Meteorology, V. Bjerknes, Norway (Chapman, Great Britain); Oceanography, Knudsen, Denmark (Helland-Hansen, Norway); Vulcanology, Michel-Lévy, France; Hydrology, Smetana, Czechoslovakia (Luetschg, Switzerland). The secretaries of Associations, in the same order (with new elections indicated in brackets), were: Perrier, France; Rothé, France; Wehrlé, France (J. Bjerknes, Norway); la Cour, Norway; Proudman, England; Malladra, Italy (Signore, Italy); Dienert, France (Frolow, France).

The administrative business of the Union included the election of Dr. D. la Cour (Denmark) as its next president; the continuance of the national subscriptions to the Union at the same rate as for the period 1933–36 (about £160 to £800 per annum according to the national population) and substantially the same division as before of the Union funds between the seven Associations; the adoption of new statutes together with new by-laws, in place of the existing statutes, and the acceptance of an invitation from the United States of America to hold the next General Assembly in Washington in 1939.

Structure of Proteins and of Certain Physiologically Active Compounds

By Dr. D. M. Wrinch, Mathematical Institute, Oxford

RECENT studies have discovered the fact that a number of classes of physiologically active compounds (for example, the carcinogens, the sterols and bile acids, the sex hormones, the heart poisons) have all a similar framework[1]. Two questions then arise. (1) What is the significance of this similarity of structure ? (2) Why do these compounds which have certain similarities of structure possess physiological properties so different as those, for example, of the sex hormones and the cardiac poisons ? In answer to these questions we suggest that for certain types of interaction with the organism it is necessary (though not sufficient) that a molecule possess an affinity for, in the sense of superposability on, some 'substrate' in the organism. This suggestion, which simply gives precise expression to an idea long since well established in physiological chemistry[2], accounts for the similarity of framework. The particular nature of the interaction may then be attributed to the degree of unsaturation (compare specially the carcinogenic hydrocarbons and cholesterol), to the occurrence of a lactone ring and to the occurrence and particular distribution of carbonyl, hydroxyl and methyl groups in the compounds in question.

In the course of an orderly search for some suitable substrate sufficiently widely distributed through the organism and yet possessing a common molecular surface pattern or mosaic, attention is naturally directed first to the proteins. More than any other chemical substance proteins have an inevitable connexion with living matter ; wherever there is living matter there proteins are found ; wherever there are proteins there is or was living matter[3]. Undeniably, proteins are connected with the physicochemical changes which occur during the life of an organism. They form a more or less permanent part of it, since only under conditions of starvation are they oxidized to release the energy required to perform the work of the cell[4]. Furthermore, many facts belonging to protein chemistry (for example, the interchangeability of proteins as substrates for certain enzymes) suggest that proteins can possess a common surface pattern. For these reasons there is an inherent plausibility in postulating that the substrate whose mosaic is to have a geometrical affinity to the classes of compounds mentioned above is protein*.

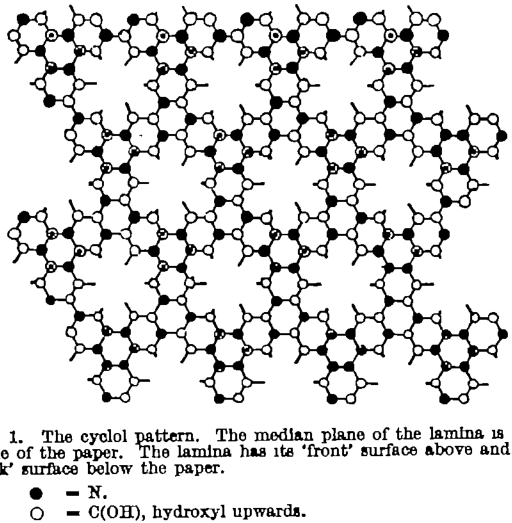

FIG. 1. The cyclol pattern. The median plane of the lamina is the plane of the paper. The lamina has its 'front' surface above and its 'back' surface below the paper.

● = N.
○ = C(OH), hydroxyl upwards.
○ = C(OH), hydroxyl downwards.
○— = CHR, direction of side chain initially outwards.
○- = CHR, direction of side chain initially upwards.

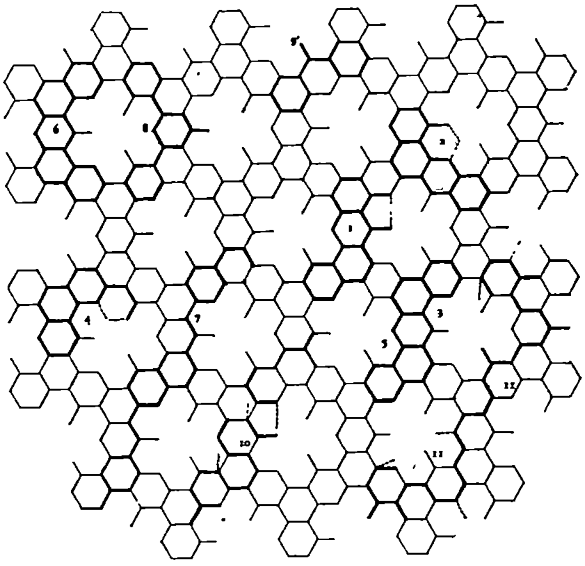

FIG. 2.

The fundamental fact about the structure of proteins is that they consist of condensations of amino (and imino) acid molecules. Leaving aside the intermediate stages, polypeptides or substituted diketopiperazines, which may or may not occur in biosynthesis, and which in any event yield an identical pattern by means of cyclization and polymerization respectively, we find that it is possible to construct a simple polycondensation pattern of the amino acids. This 'cyclol' pattern depends upon one and only one assumption, itself a simple extension of Fischer's classical hypothesis, namely, that amino acids can condense by means of single, double and triple peptide links. Given this assumption, the 'cyclol' theory of protein structure follows by means of purely logical and mathematical arguments[5]. The plane form of the cyclol pattern is shown in Fig. 1. Owing to the lævo character of all the amino and imino acids in proteins[6], the cyclol pattern is a dorsiventral lamina in the sense that from one surface all the side chains emerge, whereas the other surface is free from side chains. Here, then, is further evidence that it is possible for proteins with the most diverse chemical composition to share one common surface pattern, namely, that on the surface free from side chains. A number of the requirements of protein chemistry are thereby met; and the type of substance which is *a priori* most likely to be involved in reactions with the physiologically active compounds listed above, turns out actually to possess a common mosaic. Affinity with this mosaic then seems likely to be the explanation of the similarity of structure of these compounds. We have now to consider the details of this mosaic and its relation to the molecular framework of these compounds. On this occasion the question is discussed with reference to the carcinogens. The considerations adduced may also be applied to the sterols, the sex hormones, etc.

---

* In a recent research on the effect of methyl cholanthrene on mouse fibroblasts *in vitro* (NATURE, 138, 291 ; 1936), Hearne finds that this carcinogen induces chromosome pairing and chiasma formation in somatic cells. In view of the protein in the nuclear membrane and in the chromosomes themselves (see Wrinch, NATURE, 134, 978 ; 1934. ibid., 135, 788 ; 1935), this result affords some support for the suggestion that the 'substrates' upon which carcinogens act are protein in nature.

It will give a fair picture of the situation as it stands to-day with respect to carcinogens if we consider the following substances, which are listed in a roughly decreasing order of potency: (1) methyl cholanthrene[7]; (2) 1,2-benzpyrene[8]; (3) 1,2,5,6-dibenzanthracene[9]; (4) 3,4-benzphenanthrene[10]; (5) 1,2,5,6-dibenzacridine[10]; (6) 3,4,5,6-dibenzacridine[10]; (7) 2-(*p*-aminostyryl)-6-(*p*-acetylaminobenzoylamino)-quinoline methoacetate[11]; (8) triphenyl benzene[12]; (9) tetraphenyl methane[13]. All these structures have a geometrical affinity to the cyclol pattern which is shown in Fig. 2 with its 'back' surface upwards so that all the side chains emerge below the plane of the paper. The frameworks of (3), (5), (6) and (7) are completely superposable on this mosaic: that of (2) and of (4) are superposable except for one atom, as shown by dotted lines. The case of methyl cholanthrene is interesting, in that complete superposability can be obtained by including an imino acid residue in the cyclol pattern. Alternatively, the framework is superposable, as shown in Fig. 2, except for the distortion of the five-membered ring, shown by the dotted line. Triphenyl benzene is superposable to the extent of 21 of its 24 carbons: furthermore, it can attain this superposability in three different ways. The position with respect to tetraphenyl methane is rather different since this compound is not even approximately plane. In Fig. 2, (9) shows part of its skeleton: 14 of its 25 carbons are superposable in the cyclol pattern. Since this molecule is non-planar[13], the possibility of the superposition of these 14 atoms on the cyclol pattern requires that the cyclol pattern shall not be plane at that point, but take up an orientation in which two neighbouring diazine rings do not share the same median plane, but have median planes making the tetrahedral angle with one another. The affinity of (9) to proteins is therefore not to the plane cyclol pattern as shown in Figs. 1 and 2, but to the general three-dimensional cyclol pattern, which has already proved useful in devising structures for the globular proteins[14].

This preliminary study of the affinities of the carcinogens for the cyclol mosaic presents two points of interest. Evidently a structure may be partially or even wholly superposable on the cyclol pattern without possessing the phenanthrene nucleus. Further, since the cyclol pattern need not be planar, there is no reason to expect that all carcinogens are planar. The substance (9), far from being an anomaly, may be the first of a new type of non-planar carcinogens which have a geometrical affinity to the non-planar cyclol pattern.

The suggestion that ordinal similarity of molecular structures is a necessary (though not sufficient) condition for certain types of physiological interaction, and that the special nature of these interactions is then determined by special atomic groupings, is in good accord with phenomena belonging to many fields of physiological chemistry. As an example we cite the case of the specific polysaccharides of types I, II, III, IV pneumococcus, which are antigenic when coupled to a protein, although the antigenic reaction is specific to the polysaccharides[15]. We may suppose that the importance of the protein constituent resides in its superposability on a protein substrate, the nature of the action being conditioned by the polysaccharide. It is perhaps appropriate to direct attention at this point to the far-reaching consequences which are logically entailed if, as is now suggested, proteins of different chemical composition can yet possess a common surface pattern.

The geometrical relationship of the cyclol pattern and the framework of the physiologically active compounds mentioned above further suggest that proteins may be the seat of biosynthesis. We suggest that cholesterol and carotene, for example, are formed in the organism by superposition on a cyclol template. The 'ingredients' may be pictured as long carbon chains which on superposition cyclize as shown in Fig. 2 (see (10) for cholesterol and (11) for carotene) or possibly as shorter carbon chains which then join up intermolecularly.

It appears that there is an important field for experimental work in the study of the processes of (intramolecular) cyclization and (intermolecular) polymerization with special reference to the use of large molecules of various types, including proteins, as templates. Such researches may throw light upon the mechanism at work in Nature which, from a vast array of possible structures, selects in fact only a few. Incidentally, they should confirm or refute the present suggestions, which amount to a simple interpretation of this mechanism in terms of the common mosaic of proteins predicted by the cyclol theory of protein structure.

Administration and Technology in Industry

IN a paper on "The Place and Function of the Administrative and Technical Worker in the New Forms of Economic Structure" before Section F (Economic Science and Statistics) of the British Association on September 14, Mr. S. W. Smith directed attention to the growth and change of personnel which have accompanied the changes in the structure of industry and in industrial practice and technique in the last thirty-five years, particularly since the War. The mechanization and rationalization of industry have been accompanied by a significant growth in the importance of the technicians and scientific workers and the administrative staff, with a simultaneous reduction in the significance and proportion of unskilled labour and of controlling and directing owners of business. The bulk of the reorganization and modernizing work involved in the transformation of industry has been carried out by the technical and administrative staffs, and their importance has been further enhanced by the marked tendency for the proportion of professional, technical and administrative staffs to increase steadily in proportion to the remainder.

In support of his argument Mr. Smith referred to figures from the 1930 Census of Production showing that the administrative staff in productive concerns increased by 12·3 per cent between 1924 and 1930, excluding all those employed in shops, wholesale houses, banks, insurance companies, etc. Compared with 1907, while the total of operatives fell from 6,493,129 to 6,417,514, that of the administrative, clerical and technical staff rose from 490,947 to 723,920. Between 1911 and 1931, wages paid in industry receded from 42·5 to 41 per cent of the total, whereas in the same period salaries increased from 12 to 24 per cent. Between 1921 and 1931 professional workers increased by nearly 21 per cent, the increase in clerical staff being even more striking. Throughout the motor industry, the electrical and radio industries, and all branches of chemical industry the professional, scientific, technical and administrative staff played a dominant role, and it may be said that large business owes its existence chiefly to them. In turn, large business has provided them with the best and most abundant opportunity for their knowledge and skill. Virtually they constitute a new class, the most significant products of modern technique in industry and commerce, and in factory or office everywhere they occupy key positions.

The efficient functioning of large-scale business, whether manufacturing or distributive, largely depends upon these workers, who not only supply initiative and active control but also a constant flow of new ideas and inventions. Much the same holds with public utility corporations and municipal enterprises. Mr. Smith directed attention to the displacement or substitution of company proprietors or directors by responsible public officials, and the stipulation that a director should hold no shares whatever in order to secure that his dominant concern should be the public interest.

These changes have led to the question of training for industrial administration receiving growing attention. In the Post Office, a training school has been established in connexion with its Engineering Department where probationary assistant engineers receive a course of instruction in administration and finance. The conversion of potential proprietors into salaried managers and administrators also means that the speculative outlook of profit-seeking persons is replaced by the professional outlook with its prime interest in the efficiency of the work for its own sake. Since the salaried technician or administrator when reasonably and adequately paid tends to be interested in his work for its own sake, the functional outlook tends to replace the profit-seeking motive, care of the public interest and the spirit of service or trusteeship that of self-seeking or proprietorship.

This expansion of the administrative, technical and managerial sections of industry, with its increased stability of their income, has, however, been accompanied by a serious deterioration in the general security of all such salaried workers. The advent of unemployment among such workers who had previously been virtually immune has probably contributed to the widespread establishment among them of protective associations and trade unions, some fifty of which were represented at a Conference called a year or two ago by the National Federation of Professional Workers. Under present industrial tendencies, this increased precariousness and economic uncertainty of salaried workers is likely to continue, and its existence must be recognized in considering the significance of the place which administrative and technical workers now occupy both in industry and in society.

At a subsequent session on business administration, a number of these questions were again raised in Mr. C. A. Lee's paper on "Some Problems of a Small Manufacturing Business". The great asset of the small firm, Mr. Lee considers, is the way in which the closer contact possible with the head makes it possible for his personality to be felt right through the concern. This in itself is an important factor in developing a team spirit among the staff, which is just as important in a small as in a large firm for securing real co-operation, receptivity to new methods and keen interest in work. Moreover, the team spirit constitutes an effective check on slackness and grousing. Good leadership is most important and should endeavour to inspire the confidence that all concerned will be fairly treated, adequately paid and enjoy good working conditions. It is essential that the responsible staff should feel free to express ideas and have opportunity to advance. The problem of promotion may easily present real difficulty in a small firm. In regard to efficiency, while the small manufacturer cannot maintain the staff of experts employed by the larger firms, the use of outside consultants is a great help in introducing new ideas, and provided effective co-operation is secured with the staff, may be of real advantage in spite of the consultant's lack of knowledge of the particular business. In the discussion which followed, Mr. R. J. Mackay referred to the success which has attended the autonomous groups system described by M. H. Dubreuil before the Section in 1934.

The paper by Mr. E. S. Byng which followed discussed the claims of administration to be considered a definite profession, involving a special technique and requiring a systematic scheme of education. Empirical methods of approach can no longer be considered adequate when our economic units are so large and their administration so complex, and it has become necessary to distinguish between the trained administrator who adopts a scientific approach to his problems, and the man who continues on rule-of-thumb methods. Administration may be defined as the co-ordination and control of all the specialized activities necessary to the effective operation of an industrial or other undertaking. Administration and specialist functions are closely interwoven in the senior positions of an industrial undertaking. While, for example, the managing director may be regarded as exercising 90 per cent administrative and 10 per cent technical functions, the works manager 66⅔ per cent administrative and 33⅓ per cent technical, the sales manager 60 per cent technical and only 40 per cent administrative, it is surprising how far down the scale some proportion of administrative function is involved.

The chief characteristics of modern industrial administration may be summarized as: functional division and devolution of responsibility, involving specialization and simplification; co-ordination of activities, involving the generation of the team spirit on a large scale; and the substitution of fact analysis for guesswork, involving planning, costing and budgetary control. The impact of economic forces has driven industrialists to seek higher efficiency through the improved technique of specialists in all these departments. Their next problem is to bring about a parallel improvement in the technique of administration itself.

Mr. Byng referred to the way in which the responsibility of the administrator has been enhanced by specialized research into the conduct of industry, and stressed the importance of advances in industrial psychology and the study of human relationships. If the art of persuading men to work willingly and harmoniously is lacking, the real effectiveness of the undertaking is seriously impaired, and even complete failure may ensue. Sound laws of administration cannot be laid down without a clear understanding of human motives and desires embodying the characteristics of the group-mind, the effect of tradition, the response to varying incentives, the real causes of unrest and the emotional reactions to regulations and discipline. Accordingly, the responsibilities of the administrative function for the efficient development of industrial and commercial enterprise, for the effective use of capital and labour, and for the creation of means by which the increased wealth due to technological improvements in industry can be utilized for the greatest benefit of all concerned, carry social and economic consequences of national and indeed international importance.
